Complexity Analysis of the Cost-Table Approach to the Design of Multiple-Valued Logic Circuits

Kris A. Schueller, Member, IEEE, and Jon T. Butler, Fellow, IEEE

Abstract—We analyze the computational complexity of the cost-table approach to designing multiple-valued logic circuits that is applicable to FLL, CCDs, current-mode CMOS, and RTDs. We show that this approach is NP-complete. An efficient algorithm is shown for finding the exact minimal realization of a given function by a given cost-table.

Index Terms—Computational complexity, cost-table, cost function, logic design, minimization, multiple-valued logic, NP-complete, synthesis.

1 INTRODUCTION

The first demonstration that a logic synthesis problem is NP-complete occurred as the result of two insights. To find the minimal sum-of-products expression for a logic function, one can produce the set $S$ of all prime implicants and then use a minimal subset of $S$ to cover all minterms of the function. The latter step is a specific case of the set covering problem. Because it is a specific case, it is possible that it is not as complex as the general set covering problem. However, Gimpel [2] showed that this is not true. He showed that any instance of the set covering problem occurs as an instance of the sum-of-products problem. Subsequently, Karp [3] proved that the set covering problem is NP-complete; thus, proving that extracting a minimal sum-of-products expression is NP-complete. While complexity questions have frequently occurred in multiple-valued logic (e.g., [1], [7]), there has been no classification of the synthesis of multiple-valued functions complexity classes, e.g., NP-completeness.

The need for design techniques for multiple-valued CCD circuits, [5], inspired interest in the cost-table approach, e.g., [1], [6], [7]. In the cost-table approach, a given function is realized by selecting functions from a table and combining them. Associated with each chosen function is a cost, which can represent chip area, power dissipation, speed, etc. The cost of a realization is the sum of the costs of the component functions plus the cost of combining them. Usually, there is more than one way to realize a given function, and the goal of the design is to find a realization of lowest cost. This is called the Cost-Table Realization problem. The question posed and answered in this paper is “How does the time to solve the cost-table realization problem depend on the size of the cost-table?” We show that this problem is NP-complete.

2 BACKGROUND AND NOTATION

A function $f(X)$ is a mapping $f: D^m \rightarrow R$, where $D = \{0, 1, ..., d - 1\}$ and $R = \{0, 1, ..., r - 1\}$. When $n = 1$, it is convenient to represent $f(X)$ in the form $\langle f(0), f(1), ..., f(d - 1) \rangle$. For example, if $d = r = 4$, then $f(X) = <3, 2, 1, 0>$ is the four-variable complement function. The set of all $r$-valued functions of $n$ $d$-valued variables is $U_{d,n}$. Let $c(f)$, the cost function, be a mapping $c : U_{d,n} \rightarrow R^+$, where $R^+$ is the set of nonnegative real numbers. For example, the cost function $c(f)$ introduced by Kerkhoff and Robroek [6] for the design of four-valued CCD logic circuits correlates closely with the chip area occupied by the most compact implementation of $f$.

Given a function $f(X)$ to be realized using a cost-table, we seek a representation of the form $f(X) = f_1(X) + f_2(X) + ... + f_m(X)$, where $+$ is ordinary addition with logic values viewed as integers and $f_i$ is a cost-table function. For example, if $f_1(X) = <0, 1, 2, 3>$ and $f_2(X) = <3, 2, 1, 0>$, then $f_1(X) + f_2(X) = <3, 3, 3, 3>$. In our analysis, it is convenient to assume that the sum of two logic values does not exceed the highest logical value, $r - 1$. Thus, $+$ can be implemented as the sum mod $r$ or as truncated sum, for example. The latter is more common in practice, since it is easily implemented, e.g., in CCD or current-mode logic. The effect of this assumption is not to restrict the operations possible, but the synthesis technique. For example, $f_1 + f_2$ is not a realization of the synthesis technique because two components sum to a value greater than $r - 1$. Let $\sigma$ be the cost of realizing the sum of two functions. The cost of the realization $f = f_1 + f_2 + ... + f_m$ is

$$c(f) = c(f_1) + c(f_2) + ... + c(f_m) + (m - 1)\sigma,$$

where $\sigma$ is the cost of combining two cost-table functions.

A basis function $f$ has the property that $f(A)$ is 1 for exactly one assignment $A$ of values to $X$ and is 0 for all other assignments. Let $B$ be the set of all basis functions plus 0, the function that is 0 for all assignments of values to the variables (e.g., $<0, 0, 0, 0>$). $B$ is called the basis cost-table. $F$ is a cost-table if and only if $F \subseteq B \subseteq U_{d,n}$. Note that all functions in $B$ are needed in $F$. Indeed, if the function $f$ to be realized has the property $f \in B$, then $f$ cannot be realized, unless $f \in F$. Of all the ways to realize a given function $f$ using cost-table $F$, one realization $f = f_1 + f_2 + ... + f_m$, where $f_i \in F$, has a cost that is lower than or equal to the cost of all other realizations of $f$ using $F$. Denote realization $f = f_1 + f_2 + ... + f_m$ as a minimal cost realization of $f$. Note that there may be more than one such realization. Its cost, $c(f_1) + c(f_2) + ... + c(f_m) + (m - 1)\sigma$, is the cost of realizing $f \in U_{d,n}$ using cost-table $F$, and will be denoted as $c(f)$. Thus, whenever we seek the cost of realizing a given function $f$ using a given cost-table $F$, we assume that, of all the ways to realize a function $f$ using cost-table $F$, we choose the lowest cost realization. Formally,

$$c_f(f) = \min_{f_1 + f_2 + ... + f_m \in F} \{c(f_1) + c(f_2) + ... + c(f_m) + (m - 1)\sigma\},$$

The total cost, $T(F)$, of cost-table $F$ is

$$T(F) = \sum_{f \in U_{d,n}} c_f(f).$$

$F$ is a minimal cost-table if $T(F) \leq T(F')$, for all $F'$, such that $|F| = |F'|$, where $|F|$ is the cardinality of $F$. The term “minimal” describes the cost over all realizations of a cost-table.

The (Minimal) Cost-Table Realization, (MCR) CR, problem is:

Given a (minimal) cost-table $F$, a function $f$, and a cost function $c$, find a minimal cost realization $f = f_1 + f_2 + ... + f_m$, where $f_i \in F$. 

0018-9340/97$10.00 ©1997 IEEE
We analyze the computational complexity of the cost-table approach to designing multiple-valued logic circuits that is applicable to I2L, CCDs, current-mode CMOS, and RTDs. We show that this approach is NP-complete. An efficient algorithm is shown for finding the exact minimal realization of a given function by a given cost-table.
The (Minimal) Cost-table Decision, (MCD) CD, problem is:

Given a (minimal) cost-table $F$, a function $f$, a cost function $c$, and a target cost $P$, does there exist a realization $f = f_1 + f_2 + ... + f_m$ such that $c(f_1 + f_2 + ... + f_m) \leq P$, where $f_i \in F$?

Let $(MCD(F, f, c, P)) CD(F, f, c, P)$ denote an instance of this problem. $(MCD(F, f, c, P)) CD(F, f, c, P)$ is said to be satisfied if and only if such a realization exists. The size $K$ of an instance of $(MCD(F, f, c, P)) CD(F, f, c, P)$ is $d^r | F |$. $K$ accounts for both the function size, as well as the cost-table size. Since the MCD$(F, f, c, P)$ is a special case of the CD$(F, f, c, P)$, there is the possibility that it is not as complex. We show, however, that this is not the case.

### 3 Complexity of the Cost-Table Realization Problem

The main results are presented in two theorems.

**Theorem 1.** The Cost-table Decision problem is NP-complete.

**Theorem 2.** The Minimal Cost-table Decision problem is NP-complete.

We proceed by first showing that these two problems are within NP; that is, we show in Lemma 1 that there exists a nondeterministic Turing Machine that calculates each problem in time polynomial in the size of the problem.

Next, in Lemma 2, we show that there is a polynomial time transformation of the Knapsack problem to the (Minimal) Cost-table Decision Problem, where the former is satisfied iff the latter is satisfied. Since the Knapsack problem is known to be NP-complete, this shows that the (Minimal) Cost-table Decision problem is NP-complete.

Consider the solution of $(MCD(F, f, c, P)) CD(F, f, c, P)$ by a nondeterministic algorithm that scans $F$, choosing as many as $r - 1$ copies of each function for each of the $d^r$ possible assignments of values to the variables. This can be done in no more than $O((r - 1)d^r | F |)$ time. This algorithm can check whether the chosen function is a realization of $f$ in $O(d^r)$ time. Also, it can check whether the cost is less than or equal to $P$ in $O((r - 1)| F |)$ time. Since the size of an instance of this problem is $K = d^r | F |$, this proves the following:

**Lemma 1.** There exists a nondeterministic algorithm that solves $(MCD(F, f, c, P)) CD(F, f, c, P)$ in time that is polynomial in its size.

The Knapsack Decision problem can be stated as follows:

Given a set $Q$ of objects, a size function $s : Q \rightarrow \mathbb{Z}^*$, a value function $v : Q \rightarrow \mathbb{Z}^*$, a size $S$, and a value $V$, there is a subset $Q' \subseteq Q$ such that $\sum_{u \in Q'} v(u) \geq V$ and $\sum_{u \in Q'} s(u) \leq S$, where $\mathbb{Z}^*$ is the set of positive integers?

Let $KD(Q, s, v, S, V)$ be an instance of the Knapsack Decision problem. $KD(Q, s, v, S, V)$ is said to be satisfied if and only if such a subset $Q'$ exists. The size of an instance of this problem is $|Q|$. The Knapsack Decision problem can be transformed to an instance of the (Minimal) Cost-table Decision problem as follows:

**Definition.** Let $\Phi$ be a transformation from any instance of the Knapsack Decision problem to an instance of the (Minimal) Cost-table Decision problem

$\Phi(KD(Q, s, v, S, V)) = (MCD(F, f, c, P)) CD(F, f, c, P),$

with $F, f, c,$ and $P$ defined as follows:

1) The cost-table $F$ consists of $r$-valued functions on one $d$-valued variable, where $r = S + 1$ and $d = |Q| + 1$. Besides the $d + 1$ functions in BT, there are $d - 1$ nonbasis functions $f_1, f_2, ..., f_{d-1}$, where $f_i$ corresponds to $u_p$ the $i$th element in $Q$. Specifically, $f_i(0) = s(u_i), f_i(1) = 1,$ and $f_i(j) = 0,$ for $1 \leq j \leq d - 1, j \neq i$. We have

\[
\begin{align*}
   f_1 &= s(u_1), 1, 0, 0, ..., 0 > \\
   f_2 &= s(u_2), 0, 1, 0, ..., 0 > \\
   ... \\
   f_{d-1} &= s(u_{d-1}), 0, 0, ..., 1 >.
\end{align*}
\]

2) Function $f$ has the form

\[
f = s(S), 1, 1, 1, ..., 1 >.
\]

Since $f(0) = 1$ for $1 \leq i \leq d - 1$, each $f_i$ can be used at most once in the realization of $f$. This corresponds to the restriction that each element $u_i \in S$ is used at most once in the Knapsack Decision problem. Also, since $f(0) = S$, the sum $\sum f_i(0)$ over the $f$s used in a realization of $f$ (i.e., $s(u_i)$) must be less than or equal to $S$.

3) Let $c(f_i) = s(u_i)$, for $1 \leq i \leq d - 1$. Let the cost of functions in BT be defined as follows:

\[
c(f_i) = \begin{cases} 
0 & \text{if } f = 0 \\
ap(u_i) & \text{otherwise},
\end{cases}
\]

where $b(j) = 1$ and $b(i) = 0$ for $i \neq j$. That is, the cost of $f \in B$ is 0, and the cost of all other basis functions is the value of some object in $Q$. The cost of the constant function $\sum 0 = 0$. Let the cost, $\alpha$, of combining two functions be 1.

If $\Phi$ is a transformation to CD$(F, f, c, P)$, then any specification of the cost of a function $g$, such that $g \notin F$. If $\Phi$ is a transformation to MCD$(F, f, c, P)$, we make the additional specification that, for $g \notin F$, $c(g) = \infty$. In this way, $F$ is a minimal cost-table; i.e., no interchange of functions outside $F$ with functions inside $F$ that preserves the size of the cost-table yields a total cost lower than $T(F)$.

4) $P$ is defined by

\[
P = \sum_{u_i \in Q} c(u_i) - V + (S + d - 2)
\]

**Example.** Consider a knapsack defined as follows: Let $Q = \{u_1, u_2, u_3\}$, and let $s(u_i)$ and $v(u_i)$ be specified as in Table 1. Let $S = 5$ and $V = 6$.

<table>
<thead>
<tr>
<th>TABLE I</th>
</tr>
</thead>
<tbody>
<tr>
<td>$s(u_1)$</td>
</tr>
<tr>
<td>$v(u_1)$</td>
</tr>
<tr>
<td>$s(u_2)$</td>
</tr>
<tr>
<td>$v(u_2)$</td>
</tr>
<tr>
<td>$s(u_3)$</td>
</tr>
<tr>
<td>$v(u_3)$</td>
</tr>
</tbody>
</table>

Of the eight ways to choose subsets of $Q$, there are two that satisfy $KD(Q, s, v, S, V)$, as shown in Table 2.

<table>
<thead>
<tr>
<th>TABLE 2</th>
</tr>
</thead>
<tbody>
<tr>
<td>$Q_1 = {u_1, u_2}$</td>
</tr>
<tr>
<td>$\sum_{u_i \in Q_1} s(u_i) = 5 \leq S = 5$</td>
</tr>
<tr>
<td>$Q_2 = {u_1, u_3}$</td>
</tr>
<tr>
<td>$\sum_{u_i \in Q_2} s(u_i) = 5 \leq S = 5$</td>
</tr>
</tbody>
</table>
Applying the transformation yields a cost-table where \( r = 6 \) and \( d = 4 \) with functions as shown in Table 3. The function to be synthesized is \( f = \langle 5, 1, 1, 1 \rangle \), and \( P = 10 \). The instance of the cost-table decision problem, \( CD(F, f, c, P) \) so formed, is satisfied by exactly two realizations of \( f \), as shown in Table 4. These two realizations match left to right with \( [u_1, u_2] \) and \( [u_1, u_2] \), the subsets satisfying \( KD(Q, s, v, S, V) \). Note that the two realizations of \( \langle 5, 1, 1, 1, 1 \rangle \), one is uniquely minimal, that given in the left hand column of Table 4.

We can make the following general statement.

**LEMMA 2.** \( \Phi \) is a polynomial time transformation of the Knapsack Decision problem to the (Minimal) Cost-table Decision problem, such that \( KD(Q, s, v, S, V) \) is satisfied if and only if (MCD(F, f, c, P)) \( CD(F, f, c, P) = \Phi(KD(Q, s, v, S, V)) \) is satisfied.

**PROOF.** The proof is divided into three parts. First, it is shown that \( \Phi \) takes polynomial time. Next, it is shown that if \( KD(Q, s, v, S, V) \) is satisfied, then \( \Phi(KD(Q, s, v, S, V)) \) is satisfied (only if). Finally, it is shown that, if \( \Phi(KD(Q, s, v, S, V)) \) is satisfied, then \( KD(Q, s, v, S, V) \) is satisfied (if).

To form the cost-table \( F \subseteq U'_{d,1} \), \( \Phi \) generates \( d - 1 = |Q| \) nonbasis functions, \( d \) basis functions, and the constant function \( <0, 0, ..., 0> \). Each function can be described by a truth table with \( d = |Q| + 1 \) entries. An entry in the truth table can be evaluated in constant time. Thus, the total time needed to generate \( F \) is \( O(|Q|^2) \). A cost is then assigned to each function requiring constant time per function. Since \( s(u_i) \) can be computed in constant time, the target function \( f \) can be formed in \( O(|Q|) \) time. Finally, \( P \) requires the summation of all \( v(u_i) \), which also takes \( O(|Q|) \) time. Since each step takes at most polynomial time, the entire transformation takes polynomial time.

As preparation for the next two parts, consider

\[
\begin{align*}
& \mathbf{g} = \{ f_i \text{ if } u_i \in Q' \text{ and } 1 \leq i \leq d - 1, \\
& \mathbf{h}_i \text{ if } d \leq i \leq m \\
& \mathbf{b}_j \text{ if } u_j \in Q' \text{ and } 1 \leq i \leq d - 1 \\
& \mathbf{b}_j \text{ if } d \leq i \leq m
\end{align*}
\]

where \( Q' \) is the subset of \( Q \) that satisfies the Knapsack Decision problem and \( m = S - S' + |Q'| \), for \( S' = \sum_{u_i \in Q'} s(u_i) \). We now show that \( g_1 + g_2 + ... + g_m \), we now show that \( g_1 + g_2 + ... + g_m = f \). Consider \( g_1 + g_2 + ... + g_m \), when the variable value is 0.

\[
\sum_{i=1}^{m} g_i(u) = \sum_{u_i \in Q'} f_i(0) + \sum_{u_i \in Q'} b_i(0) + \sum_{u_i \in Q'} h_i(0)
\]

\[
= \sum_{u_i \in Q'} s(u_i) + 0 + (m - d + 1) = S' + 0 + (S - S') = f(0).
\]

When the variable value is not 0, \( g_1 + g_2 + ... + g_m \) is evaluated as follows: By the definition of \( f_i \) and \( b_i, g_i(j) = 0 \) if \( i \neq j \) and \( 1 \leq j \). Therefore, \( \sum_{i=1}^{m} g_i(u) = 1 = f(j), \) for \( 1 \leq j \leq d - 1 \).

This proves that \( g_1 + g_2 + ... + g_m = f \).

The cost of realization \( f = g_1 + g_2 + ... + g_m \) is

\[
\sum_{u_i \in Q'} s(u_i) + \sum_{u_i \in Q'} v(u_i) + 0 + (m - 1)
\]

or

\[
S' + \sum_{u_i \in Q'} v(u_i) - V' + (S - S' + |Q| - 1)
\]

where \( V' = \sum_{u_i \in Q'} v(u_i) \). From (1), the cost of this realization is

\[
P - V' + V.
\]

(only if) Assume \( KD(Q, s, v, S, V) \) is satisfied by \( Q' \). The size of this solution is

\[
S' = \sum_{u_i \in Q'} s(u_i)
\]

and the value is \( V' \). Since \( Q' \) satisfies \( KD(Q, s, v, S, V) \), \( S' \leq S \) and \( V' \geq V \). Now consider \( c_i(f) \), the minimal cost realization of \( f \) in cost-table \( F \). Because the cost of the realization \( g_1 + g_2 + ... + g_m \) is an upper bound on the minimal cost realization, \( c_i(f) \leq P - V' + V \).

Since \( V' \geq V \), \( c_i(f) \leq P \). If \( F \) is a minimal cost-table, then \( MCD(F, f, c, P) \) is satisfied. Else, \( CD(F, f, c, P) \) is satisfied.

(f) Assume \( KD(Q, s, v, S, V) = (MCD(F, f, c, P)) \), then \( KD(Q, s, v, S, V) \) is satisfied by the realization \( f = h_1 + h_2 + ... + h_l \), where \( h_i \in F \). Then,

\[
\sum_{i=1}^{l} c_i(h_i) + (l - 1) \leq P
\]

We show that the Knapsack Decision problem is satisfied for

\[
Q' = \{ u_j \mid h_j \notin BT \}
\]

To calculate the "size" of the solution, consider the function evaluated at 0; that is, \( \sum_{u_i \in Q'} h_i(0) = f(0) \). We can write

\[
\sum_{u_i \in Q'} h_i(0) + \sum_{u_i \in Q'} s(u_i) = S
\]

where the functions in the right sum are in \( BT \), while those in the left sum are not. Since \( h_i(0) \geq 0 \), the right sum in the above equation is nonnegative. Therefore, \( \sum_{u_i \in Q'} h_i(0) \leq S \) and thus

\[
\sum_{u_i \in Q'} s(u_i) \leq S
\]

To calculate the "value" of the solution, consider the cost of the realization \( f = h_1 + h_2 + ... + h_l \). Because this is a solution to \( (MCD(F, f, c, P)) CD(F, f, c, P) \).
the minimal realization of forms a sequence of cost-tables except  

\[ \sum_{i=1}^{l} c(h_i) + (l - 1) \leq P. \]

Inserting the definitions of \( P \) and \( c(h_i) \) into this equation yields 

\[ \sum_{u_i < Q'} \psi(u_i) + \sum_{u_i < Q'} \psi(u_i) + l - 1 \leq \sum_{u_i < Q} \phi(u_i) - V + (S + d - 2). \]

Rearranging yields 

\[ V + \left[ l - (d - 1) + S - \sum_{u_i < Q'} \psi(u_i) \right] \leq \sum_{u_i < Q} \phi(u_i). \]

We show that the term in large brackets is 0. Thus, \( V \leq \sum_{u_i < Q'} \psi(u_i) \), and so the Knapsack Decision problem has a solution. Each of the 1 terms in \( f = [S, 1, 1, ..., 1] \) is realized by either a \( b_j \) or an \( f_i \) for \( 1 \leq i \leq d - 1 \). The \( f_i \) terms contribute \( \sum_{u_i < Q'} \psi(u_i) \) for \( f(0) \). Thus, \( S - \sum_{u_i < Q'} \psi(u_i) \) copies of \( b_j \) are needed. It follows that \( l = (d - 1) + S - \sum_{u_i < Q'} \psi(u_i) \). Thus, a solution to KD(\( Q \), \( S \), \( v \), \( S \), \( V \)) exists, such that 

\[ \sum_{u_i < Q'} \psi(u_i) \leq S \quad \text{and} \quad \sum_{u_i < Q'} \psi(u_i) \geq V. \]

Since the Knapsack Decision problem is NP-complete, Lemmas 1 and 2 prove the main result.

### 4 An Algorithm for Finding Minimal Cost

In this section, we present an algorithm, \( \text{MIN\_COST} \), for solving the cost-table problem. Next, we analyze the time complexity of \( \text{MIN\_COST} \), showing how the number of steps depends on \( K \), the size of the problem. We show that for smaller cost-tables, the complexity is exponential, while for larger cost-tables, the complexity is polynomial in the size of the problem.

#### 4.1 MIN\_COST

We present an algorithm, \( \text{MIN\_COST} \), to find the minimal cost realization of a function \( f \) using the cost-table technique. Specifically, \( \text{MIN\_COST}(F, f) \) finds a realization of \( f \) with minimum cost, \( c(f) \), given any cost-table \( F \subseteq U_{\bar{d}, \bar{s}} \) and any function \( f \in U_{\bar{d}, \bar{s}} \). No other published algorithm is known. It is superior to the exhaustive search algorithm used in [7]. The algorithm for solving CD given in Section 3 is the nondeterministic version of a deterministic algorithm that searches exhaustively over all combinations of cost-table functions for a realization with a cost less than a given threshold. Searching for the least cost realization yields behavior that is identical to MIN\_COST.

However, it is not necessary to search over all cost-table functions. Given two functions, \( f \) and \( c \), let \( e \equiv f \) mean that for every assignment \( A \) of values to the variables, \( e(A) \leq f(A) \). It follows that, unless \( e \equiv f \), \( e \) will never be used in a realization of \( f \). Let \( E = \{ e \mid e \equiv f \} \). \( (E, \equiv) \) is a partially ordered set \( i \), and the elements in \( E \) can be indexed such that, for all \( c_f \leq c \), \( c_f \leq c \), then \( j \leq k \).

Then, \( c_f = 0 \) (the constant 0 function) and \( c_{F_{i+1}} = f \). Let \( I = (F \cap E) - BT \). \( I \) consists of all functions in cost-table \( F \) that are potentially in the minimal realization of \( f \), excluding functions in \( BT \). \( \text{MIN\_COST} \) forms a sequence of cost-tables \( BT \) \( F_0 \subset F_1 \subset ... \subset F_{|I|} \), such that \( F_i - F_{i+1} = \{ f \} \), where \( f \in I \). \( \text{MIN\_COST} \) begins by initializing \( c_f(e_f) \) to \( c_{F_0}(e_f) \), for \( 0 \leq j < |E| \). Then, for each cost-table \( F_i \), where \( 1 \leq i \leq |I| \), \( c_{F_i}(e_f) \) is computed for each \( e_f \in E \). When \( \text{MIN\_COST} \) reaches \( F_{|I|} \), it has found a minimal cost realization of the given function \( f \) in cost-table \( F \).

\( \text{MIN\_COST} \) only checks for one use of \( f_i \) in the realization of any \( e_f \). A complication arises if \( f_i \) is required more than once in the minimal realization of some function \( e_f \). Consider the case where \( e_f = f_i + f_j + e_r \) and \( e_r = f_i + e_r \). Since \( e_r \equiv f_i \equiv e_r \), the ordering over \( E \) requires that \( r \leq s \leq k \). So \( c_{F_0}(e_r) \) will be calculated using \( c_{F_0}(f_r) \) and \( c_{F_0}(e_r) \), but the cost of \( e_r \) will have already been updated using the functions \( f_i \) and \( e_r \). Therefore, algorithm \( \text{MIN\_COST} \) correctly computes the cost of functions which use multiple copies of cost-table functions.

#### 4.2 The Time Complexity of MIN\_COST

##### 4.2.1 The Time Complexity for a Single Function

\( \text{MIN\_COST} \) consists of two steps. First, the cost of each \( e_f \in E \) using the basis cost-table is computed by summing over all functions in \( BT \), requiring \( d^d \) operations or \( O(d^d|E|) \) operations for all \( e_f \). Second, for each cost-table \( F_i \), the new cost of each \( e_f \) is computed, requiring at most \( O(d^d|E|) \) operations per cost-table. Since there are \( |I| \) cost-tables, the entire algorithm has time complexity \( O(d^d|I|) \). (The algorithm is shown in Table 5.)

In [7], cost-tables for one-variable four-valued functions were analyzed in order to study heuristics for finding minimal cost-tables. We can conclude that \( \text{MIN\_COST} \) works well for cost-tables for such functions with sizes as small as five and as large as 256.

##### 4.2.2 The Time Complexity as a Function of Input Size

From the previous analysis, the time complexity of \( \text{MIN\_COST} \) is polynomial in \( |E| \). We now consider the relationship between \( |E| \) and the size of the Cost-Table Decision problem \( K = d^d|F| \).

Let \( F \) be a cost-table of size one larger than the basis cost-table; therefore \( |F| = d^d + 2 \). Let \( f \), the function whose cost we wish to minimize, be the constant \( r - 1 \) function, so \( E = U_{d}^{d} \), and \( |I| = 1 \).

In this case, the time complexity of \( \text{MIN\_COST} \) is \( O(d^d r^d) \), while the size of the problem is \( K = d^d(r^d + 2) \). Thus, \( \text{MIN\_COST} \)'s time complexity is \( O(K^{d}) \).

As the size of the cost-table \( |F| \) increases, the time complexity of \( \text{MIN\_COST} \) becomes polynomial in \( |F| \). In the limit, \( F = U_{d}^{d} \), and the time complexity of \( \text{MIN\_COST} \) becomes \( O(d^d(r^d + 1)) \), while the size of the problem is \( K = d^d(r^d) \). Thus, \( \text{MIN\_COST} \)'s time complexity, \( O(K^{d}) \), is polynomial in the size of the problem when the cost-table is sufficiently large (approaching \( U_{d}^{d} \)).

##### 4.2.3 The Time Complexity for All Functions

In the process of finding a minimal cost of function \( f \), \( \text{MIN\_COST} \) finds a minimal cost realization for all functions \( e_f \in E \). If \( f \) is chosen to be the constant \( r - 1 \) function, then \( e \equiv f \) for all functions \( e \in U_{d}^{d} \), so \( E = U_{d}^{d} \). Using the previous analysis, a minimal cost realization of all functions can be found in \( O(d^d|F - BT(r^d)|) \) time by \( \text{MIN\_COST} \). Thus, \( \text{MIN\_COST} \) provides a more efficient alternative to exhaustive search algorithms, as demonstrated in analyzing various cost-tables [7].

</table>

5 CONCLUDING REMARKS

During the past 15 years of research on cost-tables, there has been no computationally tractable algorithm for finding minimal cost realizations of given functions. We show that this problem is NP-complete. We also show that restricting the cost-tables to be minimal (the total cost of realizations by such cost-tables is minimal) produces no relief; the problem is still NP-complete. This result represents compelling evidence for the value of heuristic methods for cost-tables.
