Prevention of Infections Associated With Combat-Related Extremity Injuries

Clinton K. Murray, MD, FACP, FIDSA, William T. Obremkey, MD, MPH, Joseph R. Hsu, MD, Romney C. Andersen, MD, Jason H. Calhoun, MD, FACS, Jon C. Clasper, MBA, DPhil, DM, FRCS(Ed), (Orth), Timothy J. Whitman, DO, Thomas K. Curry, MD, Mark E. Fleming, DO, Joseph C. Wenke, PhD, James R. Ficke, MD, and the Prevention of Combat-Related Infections Guidelines Panel

Abstract: During combat operations, extremities continue to be the most common sites of injury with associated high rates of infectious complications. Overall, ~15% of patients with extremity injuries develop osteomyelitis, and ~17% of those infections relapse or recur. The bacteria infecting these wounds have included multidrug-resistant bacteria such as Acinetobacter baumannii, Pseudomonas aeruginosa, extended-spectrum β-lactamase-producing Klebsiella species and Escherichia coli, and methicillin-resistant Staphylococcus aureus. The goals of extremity injury care are to prevent infection, promote fracture healing, and restore function. In this review, we use a systematic assessment of military and civilian extremity injury trauma data to provide evidence-based recommendations for the varying management strategies to care for combat-related extremity injuries to decrease infection rates. We emphasize postinjury antimicrobial therapy, debridement and irrigation, and surgical wound management including addressing ongoing areas of controversy and needed research. In addition, we address adjuvants that are increasingly being examined, including local antimicrobial therapy, flap closure, oxygen therapy, negative pressure wound therapy, and wound effluent characterization. This evidence-based medicine review was produced to support the Guidelines for the Prevention of Infections Associated With Combat-Related Injuries: 2011 Update contained in this supplement of Journal of Trauma.

METHODS

A MEDLINE search using PubMed from the US National Library of Medicine National Institutes of Health was performed using the key words “extremity,” “orthopaedics,” “military,” “combat,” “infection,” “prevention,” “osteomyelitis,” “negative pressure wound therapy,” “fixation,” “irrigation,” “debridement,” “antimicrobial,” “oxygen,” “culture,” “bacterial,” “fungal,” and “wound infection” with an emphasis on June 2007 through January 1, 2011. We also cross-referenced published bibliographies for additional manuscripts. In addition, we analyzed ongoing research projects with data published in abstract form or preliminary draft manuscripts for inclusion in the guidelines.

Epidemiology/Microbiology of Wound Colonization and Infection

The primary complication associated with combat-related extremity injuries is infection. Approximately 15% of patients develop osteomyelitis, and ~17% of those infections relapse or recur.10 Many of the traditional host factors associated with increased risk of extremity injury infections are not present in young, healthy military personnel.18 Therefore, infections are likely to be related to the mechanism of injury, presence of orthopedic devices, fracture severity (Type), site of injury, antimicrobial agents received, infection prevention strategies employed, surgical care, environmental contamination, and infecting pathogens, especially those that are resistant to antimicrobials.10,19–22 The bacteria infecting these wounds have included multidrug-resistant (MDR) bacteria such as *Acinetobacter baumannii*, *Pseudomonas aeruginosa*, extended-spectrum β-lactamase-producing *Klebsiella* species and *Escherichia coli*, and methicillin-resistant *Staphylococcus aureus* (MRSA).10,19,20 Although initial infections are often complicated by gram-negative pathogens, many of the late relapses are gram-positive bacteria, commonly methicillin-sensitive *S. aureus* and MRSA.10,19,20

POSTINJURY ANTIMICROBIALS

The nature of combat-related extremity injuries results in gross contamination of the wound along with anatomic and physiologic derangement of the local tissue. In addition, there are likely systemic immune alterations from the severe trauma complicating the patient’s ability to control infection. Therefore, antimicrobial activity through systemic, and possibly local, delivery is required to prevent subsequent infections.

Timing of Antimicrobials

The current recommendation by the United States for tactical combat casualty care (TCCCC) committee is rapid delivery of oral or intravenous antimicrobial therapy at the point-of-injury. This is primarily based upon expert opinion with limited supporting military data (Table 3).23–27 Delivery of antimicrobials within a 3-hour window for limb soft tissue injuries was associated with fewer infections in comparison with those who received antimicrobials after 3 hours during the Falklands Campaign in 1982.28 During the 1973 October War in Israel, the low rates of infections were attributed to casualties on the battlefield receiving antimicrobials within 30 minutes to 60 minutes of injury.29 During the war in Afghanistan, the British military did not reveal that the timing of antimicrobials was related to infection prevention, but all antimicrobials were delivered soon after injury.30 Guidelines have recommended initiation of antimicrobials as soon as possible.16,30 Retrospective civilian studies have not shown substantial differences in rates of infection based upon timing of the delivery of antimicrobial agents, but timing is typically defined by 3 hours and 6 hours, which might not correlate with the casualty taking the antimicrobial themselves or being provided by a medic near the time of injury.31 One civilian study noted a higher infection rate (7.4%, 49 of 661 patients) if antimicrobials were given after 3 hours versus a lower infection rate (4.7%, 17 of 364) when antimicrobials were given within 3 hours.32 However, this was not confirmed in other large studies, and care must be taken in general when comparing civilian and military trauma as the mechanism of injury can vary dramatically (i.e., motor vehicle crashes vs. blast injuries).33–35 In addition, one of these studies was limited by lack of follow-up because many patients with Type IIIB and IIIC fractures being transferred to tertiary care hospitals for definitive management.33
Animal studies have shown that the earlier antimicrobials are provided, the more effective they are at preventing infections, especially in the first couple of hours after injury.36–41 (Joseph C. Wenke, personal communication).

**Antimicrobial Agents of Choice**

The choice of antimicrobials was selected based upon a review of prospective and retrospective clinical trials taking into consideration the bacteria likely associated with wound contamination in the combat zone (Table 4). In the previous guidelines, we recommended the use of the first-generation cephalosporin cefazolin because of its antibacterial coverage of likely infection pathogens and its use as the standard of care in the United States for extremity trauma.16 This has remained the therapy of choice, without enhanced anaerobic or aerobic gram-negative bacterial coverage. In addition, dose modification and methods of delivery are outlined more specifically in this updated guideline.

Antimicrobials initially provided by the surgeon are selected to eradicate virulent bacteria likely inoculated into the wounds at the time of injury to prevent local and systemic infection. Yet, multiple studies reveal that the bacteria contaminating open fractures at the time of injury are not the same bacteria cultured from infected open fractures after debridement.42–46 Instead, these infections are thought to be caused by hospital-acquired bacteria.42,47 Nosocomial infections with late onset wound infections were well described during World War II.48–50 In the Korean War, pathogens infecting wounds within 8 hours of injury included *Clostridium* species along with gram-positive and gram-negative pathogens.51 In addition, wounds appeared to have varying types of bacteria isolated from them over the course of a serviceman’s hospitalization, but infections only occurred when wounds had necrotic tissue remaining.52 During the Vietnam War, there was a transition over 5 days from an even mix of gram-negative and gram-positive bacteria within wounds at the time of injury to primarily gram-negative pathogens, notably *P. aeruginosa*, despite (or because of) broad spectrum antimicrobial therapy (typically penicillin and streptomycin) active against the bacteria initially found in the wound.53 Notably, wound cultures did not always correlate with matching blood cultures, and infections primarily occurred in wounds with necrotic tissue remaining. Bacteria recovered in Japan, ~7 days after injury, had a predominance of *P. aeruginosa* and *S. aureus* followed by *Enterobacter* spp. In addition, when comparing the susceptibility patterns of these organisms over time, it appeared that antimicrobial resistance increased over the course of their hospitalization.54 The presence of these pathogens remained in wounds upon arrival in the United States.55 During the wars in Iraq and Afghanistan, one study found that cultures from wounds at the time of injury reveal a predominance of gram-positive bacteria without MDR gram-negative rods.56 Overall, numerous wounds appear to be colonized and possibly infected upon reaching care within the United States or England with the burden of MDR pathogens increasing over time, as appears to have occurred in previous wars.10,19–21,57,58

The International Committee of the Red Cross (ICRC) recommends intravenous penicillin for compound fractures, amputations, and major soft tissue wounds.59 The British military has traditionally provided penicillin-based regimens at the initial time of surgery, including intravenous amoxicillin/clavulanate for abdominal injuries; however, there is debate as to the ideal agent.21,60 The Israelis’ management of injuries (predominantly from blasts) has included a combination of cephalexin and metronidazole intravenously followed by oral therapy.61

Among civilian trauma care, a Cochrane review indicated that antimicrobials were protective against early infection compared with no antimicrobials (relative risk 0.41, 95% confidence interval 0.27–0.63; absolute risk reduction of 0.08, 95% confidence interval 0.04–0.12; and number needed to treat of 13).62 This effect was attributed to the activity of β-lactams antimicrobials against streptococci and staphylococci. The Eastern Association for the Surgery of Trauma guideline committee concluded that antimicrobials were useful, but further work was needed, especially regard-

Enhanced Gram-Negative Coverage

A major area of controversy in the selection of postinjury antimicrobials involves the role of additional gram-negative coverage for Type III fractures. Prospective studies with ciprofloxacin have shown no improved outcomes and actually worse outcomes for Type III fractures in comparison with cefamandole and gentamicin. There is also in vitro and animal data which has associated fluoroquinolone use with impaired fracture healing. The role of additional aminoglycoside coverage was only assessed prospectively in one study evaluating no antimicrobials, penicillin plus streptomycin, and cefalothin for 10 days. That study did not describe the types of fractures. There was a 13.9% infection rate in the placebo group (11 of 79 wounds), 9.7% in the penicillin plus streptomycin group (9 of 92 wounds), and 2.3% in the cefalothin group (2 of 84 wounds) (no significant difference between placebo or penicillin plus streptomycin group \( p = 0.45 \) but significant difference between cefalothin and placebo and penicillin plus streptomycin groups \( p < 0.05 \)). Cultures were wound swabs but were not obtained for clinical evidence of infection. The bacteria in the penicillin plus streptomycin had the highest rate of recovered resistant pathogens after therapy. Interestingly, the cultures from the placebo group for pathogenic bacteria remained stable around 40% before antimicrobials until wound closure, whereas for the penicillin plus streptomycin group, pathogenic bacteria increased from 32% before surgery to 83% at wound closure. For the cefalothin group, bacteria recovery was 33% before antimicrobials and negative at the final wound closure culture. Although this study by Patzakis et al. has been referred to as prospective research supporting the use of enhanced gram-negative coverage, the reported results do not appear to support this recommendation. The data supporting the recommendations for aminoglycosides are typically cumulative studies that includes this prospective study just mentioned in combination with a retrospective study in which a combination of cefamandole plus tobramycin in 109 wounds had five infections (4.5%). An additional argument that has been made is based upon a prospective study comparing clindamycin versus dicloxacin with high rates of failure with Type III fractures. The authors propose that success rates could be improved by the addition of gram-negative coverage. Notably, an evaluation of possible infecting pathogens (removing likely skin pathogens such as diptheroid,
micrococcus, Bacillus species, and Streptococcus viridians) recovered from initial wound swabs were 35% gram-negative and 65% gram-positive. Clinical failure included pathogens that should have been adequately covered with initial regimens. Overall, these studies support adequate irrigation and debridement as primary therapy, with antimicrobials as adjuvants relegating later infections to primarily nosocomial transmission with antimicrobial potentially selecting pathogens.

Given the MDR nature of the gram-negative bacteria found to be subsequently infecting combat casualties’ injuries after the current antimicrobial regimens were used in the combat zone (e.g., cefazolin and levofloxacin or aminoglycoside), it is currently not clear whether the use of fluoroquinolones with enhanced gram-negative activity or aminoglycosides is resulting in the selection of these resistant pathogens, as shown in the civilian literature. Although not rigorously evaluated, data derived from the Yom Kippur War indicated that overly broad spectrum antimicrobial agents led to the development of infections with resistant bacteria. Those authors proposed that the severity of combat trauma wounds and contamination “leads toward the temptations to ‘sterilize’ the wound with massive doses of antimicrobials and favors a false security with less reliance on good surgical technique.”

If an aminoglycoside is to be used to “enhance gram-negative coverage,” it will be a challenge to determine which agent to use based upon the varying resistance profiles of the gram-negative rods being recovered from combat-related extremity injury infections. For P. aeruginosa and E. coli isolates from patients managed on the US Comfort, 94% were amikacin susceptible, and only 40% were susceptible to gentamicin or tobramycin. For Enterobacter species, 78% were gentamicin susceptible, whereas 40% were amikacin or tobramycin susceptible. If aminoglycosides use is implemented, daily dosing appears adequate, at least for gentamicin; however, higher doses might be required in a severe trauma patient, especially with these MDR bacteria.

Addition of Penicillin for Dirty Wounds

Justification for penicillin therapy has traditionally focused on gas gangrene infections or Streptococcus pyogenes (Group A streptococci). During World War I, there was a 5% incidence of gas gangrene, with 28% mortality; during World War II, the incidence ranged between 0.3% and 1.5%, depending upon the combat zone, with 15% mortality. During the Korean War, there were no reported cases of mortality as a result of this complication. This decrease was largely attributable to decreasing the time from injury to definitive care and adequate surgical debridement, not specific antimicrobial therapy. In the current era, there is some controversy about the use of penicillin after trauma. The Eastern Association for the Surgery of Trauma practice management guidelines for civilian injuries recommends high-dose penicillin when there is concern for fecal/clostridial contamination such as in farm-related injuries. However, penicillin therapy is discouraged by the Surgical Infection Society regardless of the mechanism of injury. The primary reason for not providing penicillin is the rarity of gas gangrene seen among wounds, especially combat-related extremity injuries in wartime as a result of aggressive surgical management and delayed primary closure. To date, no cases have been described in Iraq or Afghanistan. Of increasing concern is the increase in vitro resistance to penicillin in Clostridium species and limited animal data that reveal no improved outcomes with antimicrobial therapy for gas gangrene in comparison with untreated controls. Finally, other antimicrobials, typically provided during extremity wound care by physicians, have adequate Group A streptococci coverage limiting the utility of additional penicillin coverage.

Point-of-Injury Tactical Combat Casualty

A panel of military trauma experts published a list of antimicrobials that were recommended as part of TCCC or care provided at the point-of-injury. These include oral moxifloxacin and intravenous/intramuscular ertapenem or cefoxitin. Although the ICRC, the British military, and the Israeli military recommend various antimicrobials for combat-related injuries, these are not designed to be given at point-of-injury by the patient or the medic but upon evaluation by definitive medical personnel often times during the medical evacuation flight.

The core issues surrounding the determination of the ideal point-of-injury field antimicrobial is multifactorial. As addressed in articles assessing point-of-injury antimicrobial agent, the goal is to include agents that are active against the likely infecting pathogen for the body part injured along with agents that are stable and able to be delivered in a reasonable manner on the battlefield without possible adverse events to the patient. A recent study evaluating point-of-injury antimicrobials by Army Rangers did not appear to show a clear infection prevention benefit, although the numbers were small. Of note, no increase in colonization or infection with MDR bacteria was noted nor were there medication toxicities reported. There are clear arguments for choosing an agent with focused antibacterial spectrum of activity; however, it appears the antimicrobials recommended by the TCCC Committee are not causing harm and might be beneficial.

Dosing of Antimicrobials

To better optimize antimicrobial pharmacodynamics and pharmacokinetics, higher doses of antimicrobials are being recommended for perioperative antimicrobials to prevent surgical site infection. Most recommendations for perioperative antimicrobials are for a cefazolin dose of 2 g with some recommendations being weight-based: 1 g for those ≤80 kg (176 lbs), 2 g for those 81–160 kg (177–352 lbs), and 3 g for those >160 kg (>352 lbs). The package insert for cefazolin does recommend higher dosing (1–1.5 g every 6 hours) for severe, life-threatening infections with dosing up to 12 g per day being given. Given the volume of distribution in a trauma patients and the size of the typical US servicemember, a 2 g dose of cefazolin is recommended and appears to be safe.
Duration of Antimicrobials

The ICRC recommends a total of 5 days of antimicrobial therapy after injury, which is similar to the Israeli recommendation of 5 days after missile injury.59,61 Per the ICRC, if redebridement is performed instead of delayed primary closure, antimicrobials should be stopped if there are no signs of infection or local inflammation. If patients present after 72 hours or are injured as a result of antipersonnel landmines, then the addition of metronidazole in an intravenous form for 48 hours followed by oral therapy until delayed primary closure is suggested. Most authors and guidelines focusing on civilian injuries recommend 24 hours to 72 hours of postinjury antimicrobial therapy depending upon severity of injury, with shorter durations for Type I fractures and longer durations for Type III fractures.30,63,64,90 Prospective guidelines for point-of-injury antimicrobials for those unable to take oral agents (shock, unconscious, or penetrating torso injuries), the recommendation is for delivery by intravenous (IV) or intramuscular (IM) route.24,25,102 IO antimicrobial delivery has not been systematically studied in military populations or trauma patients.103,104 In animal studies, those antimicrobials that are highly protein bound have been associated with lower serum concentrations with IO delivery than IV delivery.105 Both ceftazolin and ertapenem are highly protein bound antimicrobials.106,107 IM delivery has also not been studied in military or trauma patient populations but has been used and FDA approved for ceftazolin and ertapenem.108 Antimicrobial bead pouches have also been retrospectively assessed in combination with intramedullary nails for Type II, IIIa, and IIIb tibia fractures.132 Of 50 patients who received the antimicrobial bead pouches, only 2 developed an infection, in contrast to 4 infections in the 25 patients who did not receive the pouches. In animal models, local delivery of antimicrobials appears promising.133 However, there is possible toxicity to osteoblasts associated with local delivery of some antimicrobial agents.67 Of note, antimicrobials used in combination with NPWT appears effective; however, NPWT also pulls antimicrobials out of the wound and reduces their effectiveness when compared with standard bead pouch (see NPWT section below).134 The practical use of bead pouches during aeromedical transport and frequent serial debridements remains a difficult technical challenge. It also appears that earlier delivery of local antimicrobials with earlier surgery sustained serum levels of drug.110 As bone to serum penetration ratio for ertapenem is ~0.15 and for ceftazolin it is 0.25, this low concentration of antimicrobials would limit IO or IM delivery, especially with severely ill patients and resistant bacteria.111–114

Local Antimicrobial Delivery

Local delivery of antimicrobials as a powder or solution was discouraged by Alexander Fleming in 1919 while he served in the British Army.115 During World War II, antimicrobials were shown to be more effective if given systemically than through local delivery.116–118 During the Vietnam War, topical therapy was not broadly implemented, although it appeared to be associated with lower rates of bacteria in wounds in some animal studies.119–124

During the current wars in Iraq and Afghanistan, there have been a number of reports of the utilization of local delivery of antimicrobials through beads or bead pouches, but limited comparative trials and no prospective trials are available to support this use.125 One retrospective study comparing antimicrobial bead pouch to negative pressure wound therapy (NPWT) revealed fewer infections with the antimicrobial bead pouch.126 There is extensive use of local delivery of antimicrobials through beads, which might benefit in clearing infections due to high local drug concentrations, especially those associated with biofilms or bacteria resistant to standard levels of antimicrobials.127,128 Traditionally, vancomycin and tobramycin have been the agents of choice, but other agents such as colistin have been pursued because of the MDR nature of infecting pathogens.129 A randomized, prospective study of civilian open fractures with 67 patients and 75 open fractures revealed 2 of 24 (8.3%) with antimicrobial beads alone developed an infection in contrast to 2 of 38 (5.3%) of those treated with conventional systemic antimicrobial therapy.130 A large retrospective study of open extremity fractures revealed statistically significant reduction in infections in those patients receiving local delivery of antimicrobials (tobramycin) versus those receiving only systemic therapy (12% vs. 3.7% [p < 0.01]).131 In that study, the patients with impregnated beads had their wounds closed earlier, introducing a potential bias into the study conclusions. The use of antimicrobial bead pouches has also been retrospectively assessed in combination with intramedullary nails for Type II, IIIa, and IIIb tibia fractures.132 Of 50 patients who received the antimicrobial bead pouches, only 2 developed an infection, in contrast to four infections in the 25 patients who did not receive the pouches.

In animal models, local delivery of antimicrobials appears promising.133 However, there is possible toxicity to osteoblasts associated with local delivery of some antimicrobial agents.67 Of note, antimicrobials used in combination with NPWT appears effective; however, NPWT also pulls antimicrobials out of the wound and reduces their effectiveness when compared with standard bead pouch (see NPWT section below).134 The practical use of bead pouches during aeromedical transport and frequent serial debridements remains a difficult technical challenge. It also appears that earlier delivery of local antimicrobials with earlier surgery...
might improve outcomes. Moreover, the appearance of wounds might differ with local delivery of agents, especially silver, potentially impeding clinical diagnosis of wound infection.

DEBRIDEMENT AND IRRIGATION

The gross contamination of wounds at the time of injury necessitates adequate irrigation and debridement to prevent ongoing bacterial replication. In addition, the presence of devitalized tissue is an ideal culture media, which must be adequately controlled to prevent subsequent infections.

Irrigation Fluid Additives

No combat-related extremity injury studies have evaluated the role of additives to irrigation fluid for wound management, although one study assessing NPWT in a combat support hospital did describe the role of irrigation in wound management. In addition, another study assessing minor wounds that did not require evacuation for surgical care revealed the primary importance of wound irrigation over antimicrobials.

A large, multicenter collaborative project assessing various irrigation pressures and irrigation solutions of open fractures is underway and should provide insight into the ideal irrigation strategies. This group performed a thorough review of the current irrigation literature. Preliminary data have revealed that low volume with castile soap might be beneficial. The only prospective, randomized clinical trial was limited to a single institution with relatively small numbers of enrolled participants. Patients were randomized to irrigation with a bacitracin solution or a nonsterile castile soap solution with overall findings indicating that bacitracin was no better than nonsterile castile soap but was associated with a possible increased risk of wound-healing problems. Another study limited to lacerations revealed no difference between normal saline and sterile water. Reviews and surveys of provider practice patterns indicate no clear support for additives into irrigation fluids, supporting the role of normal saline or sterile water and even potable water if the other fluids are not available. Animal studies have also supported this conclusion.

Volume of Irrigation Fluid

Although not the primary focus of a study evaluating the use of NPWT performed on casualties in Iraq, the use of pulsatile jet irrigation with at least 3 L of saline was shown to be very successful overall management strategy that decreased combat-related injury infection rates. No clear studies have proven the efficacy of the commonly used irrigation fluid bag 6 feet to 8 feet above the ground), low-pressure irrigation (5–10 psi), or high-pressure irrigation (>20 psi), although these definitions are not standardized. Overall, the reasoning behind which pressure provides the best patient outcomes was well outlined in a recent review of the subject. It showed that higher pressure initially cleans the wounds very well, but tissue and bone damage along with rebound bacterial colonization noted 24 hours after initial irrigation limits its overall positive impact. It is anticipated that the Fluid Lavage and Open Fracture Wounds multicenter, randomized trial will provide adequate data to answer this clinical dilemma. Pilot data from the Fluid Lavage and Open Fracture Wounds study does demonstrate a trend toward more wound complications with high-pressure devices.

Timing of Irrigation

Currently, there are limited data available regarding the timing of irrigation fluid delivery, as it is often lumped with routine surgical care. It is vital to have this information to show whether delivery of earlier field irrigation with point-of-injury field antimicrobials might improve infectious complications in a combat setting when evacuation is not possible. Animal studies have shown that earlier irrigation improves bacterial clearance as irrigation within 3 hours decreased bacteria counts by 70% in contrast to 52% if irrigation was delayed to 6 hours or 37% if delayed to 12 hours.

Pre- and/or Postdebridement Bacterial Wound Cultures

A study in Vietnam pertaining to cultures of wounds collected ~7 days from injury revealed that an initial negative culture was associated with 32% of patients developing a subsequent infection and a positive culture was associated with 50% of patients becoming infected. Other military studies from the Korean War, the Vietnam War, and other conflicts have described similar bacterial patterns recovered from wounds and nosocomial infections.

There are limited reports of wound cultures from casualties at the time of injury in Iraq or Afghanistan. A single study in Iraq describing 15 of 24 extremity injuries in US Servicemen found a predominance of gram-positive bacteria including occasional MRSA but recovered no MDR gram-negative bacteria at the time of injury. A limitation of this study is that patients were not followed for subsequent infections. A number of studies have assessed the role of MRSA soft tissue infections in the combat zone, including extremity injuries, but the wounding pattern and long-term complications have not been characterized. After leaving the combat zone, patients are presenting to US military hospitals with a much higher rate of MDR gram-negative bacteria colonizing and infecting wounds. It is remarkable that gram-positive pathogens are often found later in a patient’s hospital course and typically after eradicating patient’s initial colonization or infection with gram-negative
The Journal of TRAUMA® Injury, Infection, and Critical Care • Volume 71, Number 2, August Supplement 2, 2011

pathogens. It is not clear whether these gram-positive bacteria were the same pathogens initially seen at the time of injury or reflective of nosocomial transmission. A recent study using tissue biopsy culture characterization of wounds reports that 69% of 242 wound biopsies from 34 patients had no growth at the time of presentation to a US military treatment facility. The most commonly recovered pathogen in this study was A. baumannii, and of note, the incident colonization of wounds increased when examined serially over the course of 3 weeks. This study did not provide details concerning quantity of bacteria in 1 cm³ of tissue biopsied or infections associated with the wounds that underwent biopsy. Another study of British soldiers with mangled extremities revealed that bacteria initially recovered from injuries that were not the same as those later infecting wounds, but the presence of bacteria in general was possibly predictive of future infections. In addition, ~25% of war wounded patients admitted to Walter Reed Army Medical Center developed new colonization with MDR gram-negative bacteria during their hospitalization, although this study did not evaluate the infection rates.

The Surgical Infection Society guideline for prophylactic antimicrobial use provides a summary of the limited role of cultures associated with open fractures. Available civilian data support similar findings to the military, with gram-positive bacteria predominating at the time of injury and a transition to gram-negative bacteria causing ultimate infection. In addition, empiric therapy can modify the bacteria recovered. Pre- or postdebridement cultures do not appear to be consistently predictive of infection or infecting bacteria, and initial choice of early antimicrobial agents can result in bacteria that escape the initial spectrum of activity. Although postdebridement cultures have been reported to be more predictive of infection in some studies, they are not always reflective of the infecting bacteria. Some studies have supported cultures obtained 1 day after debridement that reveal the same pathogen as previously recovered are reflective of failure of debridement and subsequently high risk of infection. Additional studies have also looked at correlation with bacterial counts, notably >10⁵ bacteria per gram of tissue, but these studies did not appear to substantially correlate with infections. In addition, some studies have supported a standardized approach to culture to predict closure success. At this time, we are unable to predict which patients will go on to develop infection based upon wound cultures alone. Therefore, novel diagnostic platforms are required to describe the bioburden in the wound.

Removal of Retained Metal Fragments

Many of the weaponry systems used in combat can result in numerous fragments lodged into the body with associated tissue damage. The fragments can be associated with the deposition material that impact infectious complications. Two strategies, one in Gaza City and the other along the Afghan border, have been employed for nonoperative management of retained metal fragments in the following list of injuries: soft tissue injuries (no fractures, no major vascular involvement, and no break of pleura or peritoneum), small wound entry or exit maximum dimensions, wounds not frankly infected, and wounds not caused by mines. Management in both cases included cleaning and dressing the wounds and administration of antimetanus immunoglobulin and toxoid, penicillin IM/IV for 1 day and then orally for the next 4 days, or cephalaxin and metronidazole for 2 days intravenously and then orally for 3 days. Minimal complications occurred with these management strategies.

Management of victims of suicide bombers has included small fragments remaining in patients, but no clear management strategy for fragment removal or management strategies to prevent infections has been described. Hepatitis B virus prophylaxis, due to reports in Israel of hepatitis B virus recovered from bomber's bone fragment, has been recommended for those not previously vaccinated, due to theoretical risk of transmission. The decision not to remove small fragments has been questioned based upon a pediatric study associated with a suicide bomber in which the retained fragments became symptomatic. However, the application of this patient population and injury pattern might not equate to the military. Studies of minor gunshot wounds with fragments remaining have also shown small infection rates when managed using similar criteria to the above.

SURGICAL WOUND MANAGEMENT

Timing of Surgical Management

Historically, evacuation times have continued to decrease from 11 hours during World War II to 4 hours during the Korean War, to 3 hours during the Vietnam War, and to 1 hour to 3 hours in Iraq and Afghanistan. Traditionally, it has been recommended that open fractures undergo operative procedures within 6 hours of injury to mitigate infectious complications. Data assessing outcomes based on time to procedures are limited for combat casualties (Table 5). Among those with extremity soft tissue injuries during the Falkland Campaign, there were 2 septic patients among 20 who underwent surgery within 6 hours in contrast to 7 of the 29 patients treated after 6 hours. Nine of those 29 went to surgery after 15 hours, 3 of whom became septic. The US military experience in Somalia revealed 14 of the 16 casualties that developed infection were treated either outside of Somalia and/or after 6 hours, but long-term infectious outcomes were not described. During the war in Afghanistan, an evaluation of British military personnel with mangled extremities revealed that time to surgery had no impact on infectious complications, but this group of wounded were all evacuated rapidly to surgical care. There is military experience with delayed surgical interventions during humanitarian missions, with good outcomes being reported in host nation patients.

Wound debridement and irrigation removes foreign material, blood clots, bone fragments, and marginally vascularized tissues, which are penetrated poorly by antimicrobials and provide a good medium for bacterial proliferation. Civilian guidelines recommend that rapid surgical debridement is the primary treatment, and antimicrobials only adjuvant therapy, in the prevention of infection in open fracture management. A study by Friedrich has historically
been cited as the source for the “6-hour rule” for time to debridement of open fractures. An additional study evaluated 46 patients with Type II and III open fractures and found that 1 of 15 (7%) who underwent debridement in <5 hours from the injury became infected, whereas 12 in 32 (38%) became infected when debridement occurred >5 hours after the initial injury.163 Notably, Type III fractures comprised 33% of the <5-hour group and 53% of the >5-hour group. Multiple studies by Gustilo et al., as well as Patzakis et al., have shown that there is an increased risk of infection associated with an open fracture.32,191–193

### Timing of Wound Closure

It is currently recommended that closure of wounds in combat environments be delayed, based upon lessons learned during prior wars and supported by recent conflicts and civilian literature.59,136,196–198 However, wounds are still recommended to be closed at ~5 days if there is no evidence of infection, if it is technically possible. For vascular injuries, covering the artery with healthy tissue, to include flaps, is recommended.12,13,199 If there is a need to reconstruct an artery within a large zone of injury, tunneling the bypass or repair through clean tissue planes has been recommended. The use of autogenous tissue is also better than prosthetic, but prosthetic may need to be used in patients who do not have appropriate veins to harvest.

### Definitive Treatment

There have been an increased number of civilian trauma centers evaluating early closure of wounds due to the findings that nosocomial bacteria are typically causing infec-

tious complications. Two retrospective studies have reported immediate wound debridement and closure in open fractures. A retrospective comparative review of early versus delayed closure in open fractures showed no difference in infectious complications with primary (2%) versus delayed (4%) closure. A review in 2007 recommended primary closure if certain criteria are met: (a) debridement performed within 12 hours, (b) no skin loss primarily or secondarily during debridement, (c) skin approximation possible without tension, (d) no farmyard or gutter contamination, (e) debridement performed to the satisfaction of the surgeon, and (f) no vascular insufficiency. Unfortunately, most military injuries are not compatible with this injury pattern and criteria.

**Fracture Fixation Strategies**

Staged fixation in combat injuries has emerged as the strategy of choice in the current conflicts. Temporary external fixation has been commonly used as a bridge to definitive fixation with few significant complications. Although a few selected cases of low-energy injuries have been safely internally fixed in the combat zone, it is still considered “ill-advised” in combat-related injuries. The use of plaster and earlier internal fixation might be possible as evident by the British military experience. In addition, there can be delays associated with femoral neck fractures greater than 48 hours and talar neck fractures, which are consistent with civilian data.

Because little data on combat-related femur fractures have been published in the past 4 years, the recommendation for intramedullary nailing is supported by civilian data. Reamed intramedullary nailing of open femur fractures has been associated with infection rates of 1.8% to 5% and more. Most infections in open femur fractures occur in Type III open injuries. Based upon available literature on femur fractures, temporary spanning external fixation could be placed at Role 2-3 with skeletal traction and Thomas’s splint as alternatives. Conversion to definitive fixation at Role 4 remains controversial. Delayed conversion of external fixation to a reamed, locked intramedullary nail can be performed at Role 5 facilities after appropriate wound management.

Open tibia fractures typically have higher infection rates than open femur fractures when converted to internal fixation. Despite these moderate infection rates, the intramedullary nailing of open tibia fractures after external fixation demonstrated significantly faster union and greater range of motion with less malunion and shortening compared with casting in a randomized trial. Because of the higher prevalence of Type III open injuries of the tibia with a large proportion of blast injuries seen in military conflicts, circumferential external fixation has been used in several small previous series with favorable results. A recent series of 38 patients with combat-related Type III open tibia fractures were treated with a standardized protocol including circular (Ilizarov/Taylor Spatial Frame) external fixation. Although the overall deep infection rate was 8%, exclusion of the two infections in the four patients with IIC injuries would lower this deep infection rate to 3%. In contrast, a review of tibia fractures from Operation Iraqi Freedom treated at a single institution with intramedullary nailing demonstrated an overall infection rate of 14.3%.

The available literature on fixation of combat-related tibia fractures is the source of greatest debate in this review. External fixation is supported by literature at Role 2b to 3. Conversion to definitive fixation at Role 4 remains controversial. At Role 5, reamed, intramedullary nailing can be performed safely in selected patients with a lesser soft tissue injury. For Type III open injuries, circular external fixation has been shown to have lower deep infection rates.

Open fractures of the upper extremity seem to be best managed ultimately with plate fixation. Some high-energy open fractures may benefit from a staged protocol with initial temporary external fixation. One series of soldiers with high-energy gunshot fractures to the humerus showed a very low infection rate when managed with definitive external fixation. Although functional bracing, even with war-related humerus fractures, may be favored over external fixation, the current literature supports the use of temporary spanning external fixation or splint immobilization placed at Role 1-3 and transition to open plate and screw osteosynthesis for some open humerus fractures after soft tissue stabilization and closure.

**Negative Pressure Wound Therapy**

Wound coverage with NPWT (e.g., the Vacuum-assisted Closure [VAC] [KCI, San Antonio, TX]) has become standard of care in most military and civilian medical facilities. A review of the use of NPWT in the military was performed revealing overall success with the implementation of the device. The use of NPWT in the combat zone appears effective, but the studies are limited by a lack of adequate control arms for comparison. Studies have shown the device is feasible for intercontinental aeromedical evacuation without excess wound complications. A retrospective study of combat-related injuries that assessed the role of NPWT in comparison with antimicrobial bead pouch therapy revealed that those with NPWT had more late MRSA infections, more unanticipated returns to the operating room, and overall more surgeries until closure. The higher rate of S. aureus recovery has been previously shown in animal and human studies. This finding of better clearance of P. aeruginosa in a wound versus S. aureus might be due to virulence of the pathogen or host factors.

A randomized prospective study showed that of 58 patients with 62 open fractures those receiving NPWT had fewer infections (5.4%) compared with those not receiving NPWT (28%) (p = 0.024). Another civilian prospective randomized study evaluating the use of NPWT in 20 calcaneal fractures, 4 pilon fractures, and 20 tibial plateau fractures found no infectious differences between NPWT and standard wound care. Of note, the use of NPWT should not be employed as a substitute, or delaying method, for wound flaps, as higher rates of infections occur with delaying use of wound flaps.

In an animal model, it appears that silver-impregnated gauze with the NPWT system was associated with greater reduction in bacterial load for P. aeruginosa, and to a greater degree, S. aureus than standard gauze. However, wound tissue did not appear normal with this combination, raising
concern that use of this product might result in surgeons suspecting infection even when there is no infection present. Antimicrobial beads have been assessed with and without NPWT in an animal model of *S. aureus* infection. Although the NPWT and antimicrobial beads were associated with substantially more bacterial growth than antimicrobial beads alone, there was still activity in the wounds indicating that in certain situations, such as with possible issues with power loss to the suction apparatus, antimicrobial beads, and NPWT might be used effectively in combination (Joseph C. Wenke, personal communication). This study indicated that antimicrobial beads with NPWT were better than NPWT alone. It appeared that instillation of an antiseptic in a NPWT system was more effective than NPWT alone or with saline solution alone; however, there was decreased tissue viability with the antiseptic (Joseph C. Wenke, personal communication). Instillation of saline in conjunction of NPWT did not demonstrate a benefit over NPWT alone in a complex orthopedic injury goat model using *P. aeruginosa*. Instillation of an antiseptic, hypochlorous acid solution, did reduce the bacteria within the wound in comparison with NPWT alone, NPWT with saline instillation, or NPWT with polyhexanide and surfactant. Clinical impression of the wounds treated with instillation of the antiseptic solutions was that they had a less healthy appearance in terms of color and consistency and the subjective impression that a greater amount of nonviable tissue was debried from these wounds at each interval. Overall, antiseptic has not been widely assessed clinically, and data discouraged hypochlorous acid (Dakin’s) solution use during World War I. The use of NPWT with Dakin’s solution instillation (i.e., Dakin’s 0.025% with the NPWT set at 125 mm Hg with instillation every 2 hours for 30 seconds with dwell time of 5 minutes) has been recently implemented for injuries that primarily occur in the lush vegetative areas of Afghanistan in patients with high bilateral lower extremity injuries, often with perineal involvement that are noted to have higher rates of invasive fungal wound infections. These severely injured patients typically require massive blood volume support and are associated with injury patterns that are not amenable to very aggressive debridement during initial or follow-up surgical management. This strategy appears to be effective but needs to be systematically analyzed to determine the unique patient populations this strategy might best be applied.

Role of Oxygen Therapy

The role of hyperbaric oxygen (HBO) has been evaluated and pursued in previous wars, especially as a potential therapy for gas gangrene. A war extremity injury review, from 1991 to 1995, which included 388 combat-related Type III fractures, described the impact of HBO (99 provided HBO and 289 without HBO) on wound healing and infectious complications. Overall, the infectious complications were less when patient management included HBO. However, this effect was substantially more common among those not receiving standard wound management and antimicrobials recommended by North Atlantic Treaty Organization (NATO), and there were increased cases of osteomyelitis in the HBO-treated group. Systematic reviews of HBO therapy for acute surgical and traumatic wounds revealed a lack of high-quality, valid research. In addition to the role that hyperbaric oxygen therapy may or may not have on wound infection and/or prevention, there is ongoing concern regarding what effect low oxygenation might have on wounds during aeromedical evacuation of injured personnel from the combat zone to Germany and from Germany to the United States. A complex soft tissue injury in a goat model using *P. aeruginosa* contamination revealed that animals taken to pressures equivalent to an elevation of 8,800 feet for 7 hours became mildly hypoxic (O2 saturation of 88–92%) and their wounds had more bacterial growth than controls at ground level (Warren Dorlac, personal communication). Animals provided supplemental oxygen (to increase their oxygenation saturation to >94%) were found to have with no difference in bacterial growth compared with controls at ground level. There are prospective studies that have shown mixed efficacy in preventing infectious complications with the use of higher concentrations of oxygen concentration delivery for abdominal and pelvic surgeries, although these were not associated with elevation-induced hypoxia. Studies of the efficacy of higher oxygen concentration delivery in orthopedic trauma injuries have not been performed.

UNRESOLVED ISSUES/POTENTIAL FUTURE RESEARCH TOPICS

Role of Fungal Infections

There have been reports from the British military that casualties in the lush vegetative area of Helmand Province in Afghanistan on dismounted patrols with severe bilateral high lower extremity injuries, typically due to blast injuries and necessitating the use of tourniquets and large blood volume resuscitation, have a higher rate of invasive fungal wound infections, chiefly due to fungi belonging to the order Mucorales. In civilian trauma, a study of severe extremities injuries on farms also revealed a high rate of fungi recovered from wounds; however, the nature of the injuries described in this patient population varies from the typical blast injury seen in Afghanistan. Another study comparing timing of wound closure and antimicrobials performed quantitative cultures that revealed the presence of *Aspergillus* spp., *Mucor* spp., and other fungus at the time of initial wound management; although no subsequent infections secondary to these pathogens occurred. The role of early wound evaluation with fungal cultures, fluorescent (Calcofluor) staining, and fresh frozen and traditional histopathology looking for invasive fungal infections has not been determined. In addition, the role of early empiric antifungal therapy is not known at this time for trauma-associated wound colonization with fungi. There are data indicating that activity of local antifungal delivery with amphotericin B loaded beads is adequate for fungal treatment. Dakin’s solution (sodium hypochlorite) appears to have some activity against *Aspergillus*, but no studies assessing its activity against the Mucorales have been reported. In addition, soft-tissue toxicity associated with this agent has been described. Case series and case-control studies are underway to better characterize
these infections and to better define risk factors, diagnostic strategies, and therapies.

The Role of Inflammatory Markers to Predict Infection

During the Vietnam War, there were preliminary data indicating that elevation of creatinine phosphokinase (CK), in contrast to lactic dehydrogenase (LDH) and serum glutamic oxaloacetic transaminase (SGOT), was associated with wound infections. An evaluation of cytokines potentially associated with sepsis (from Belgrade, Serbia and Montenegro during 1999) revealed that IL-8, TNF-α, and IL-10 most specifically correlated with the diagnosis of combined trauma and sepsis. During the current wars in Iraq and Afghanistan, a number of studies have been undertaken to evaluate various wound markers and their role with wound healing and infections. Markers that have shown an association with wound dehiscence include procalcitonin in the serum, along with increased procalcitonin, decreased RANTES protein, and decreased IL-13 concentrations in wound effluent. Elevated metalloproteinase (MMP)-2 and MMP-7 serum levels and reduced levels of effluent MMP-3 were seen in wounds with impaired healing. In addition, there has been the recovery of multipotent progenitor cells from war wound muscle tissue that might have a role in tissue engineering, and other markers of inflammation have been assessed. Continued work needs to be undertaken in this area.

Role of Biofilms in Combat-Related Extremity Injuries

Although the role of biofilms in chronic infections is becoming more accepted, there are no data to date as to the role of biofilms in combat-related extremity injuries. Although numerous investigators are assessing the ability of bacteria infecting combat-related extremity injury wounds to form biofilms in vitro, and evaluating potential therapies to prevent or disrupt these, clinical studies of the impact of biofilms are still needed.

Novel Antimicrobials and Pathogen Identification

At this time, there are inadequate antimicrobials active against MDR gram-negative pathogens in the pharmaceutical pipeline, necessitating renewed emphasis in this area. The current pathogen and antimicrobial resistant diagnostic platforms rely on old technology that typically provides a relevant clinical answer for management decision in 48 hours to 72 hours. This relegates most therapy to empiricism possibly resulting in excess antimicrobial resistance. Improvements in pathogen detection and resistance determination are necessary at this time.

CONCLUSION

Extremities are the most common injury pattern during the wars in Iraq and Afghanistan with an overall high infection rate. Continued improvement in wound care is necessary to mitigate any excess short- and long-term complications. Focus on antimicrobials, wound debridement and irrigation, and surgical interventions using the current evidence-based medicine recommendations should attempt to improve outcomes, but ongoing surveillance is necessary. In addition, continued focus on unresolved issues and future areas of research are needed to improve combat casualty care.
