Information processing and evidence collection as we try to retrieve from memory evolves dynamically as memory probes change during perception of a test item, as low and high level features of the test item are retrieved from knowledge during the dynamic process of perception, and as content, content, and associative information about the test item are retrieved from event memory. This interaction occurs dynamically so that evidence leading to a task decision changes its character as new features become available at every level from perceptual features to semantic associations. We have studied this dynamic process empirically in a variety of paradigms and on the basis of the data have developed a general model of memory storage and retrieval that explains the interaction of event memory and knowledge as it develops over short periods of time (under a second). This represents a major advance in a field that usually treats retrieval of events and knowledge as separate domains of research, and that does not track the changing degree of task evidence as the dynamics change. Other major contributions were made in the domains of statistical learning, attention and perception, the dynamics of short-term recognition memory, and quantum probability decision making.

DISTRIBUTION A: Distribution approved for public release.
This grant supported empirical research and development of dynamical models of memory retrieval. In this period this subject was explored primarily in seven related domains: 1) the evolution of the interaction of storage and retrieval of event memories and knowledge; 2) the rapid dynamics of the way task evidence changes as perception and retrieval occur from both knowledge and event memories; 3) the dynamical process of decision making in short-term recognition memory; 4) short term memory for attributes of visual stimuli presented simultaneously; 5) the process of accumulating evidence about associations across trials when individual trials are each ambiguous; 6) how memory retrieval is harmed by the act of storing information during testing; 7) how seemingly irrational decision making can be interpreted in terms of humans knowledge of probability being rooted in quantum probability theory.

The first project had results summarized in a publication in our field’s major theoretical journal: Nelson, A. B. and Shiffrin, R.M. (2013). The co-evolution of knowledge and event memory. *Psychological Review, 120*(2); 356-394. We reported a general model for the dynamic interaction of event memory and knowledge, based on several studies in which knowledge for novel (Chinese) characters was developed through extensive training. The interaction of this knowledge with event memory was assessed with a knowledge task (pseudo-lexical decision), a perceptual task (perceptual identification), and an episodic recognition task (recognition memory for occurrence of a test item on a studied list). This research represented a major advance because event memory and knowledge memory are usually treated independently. The essence of the model explained how knowledge evolves through repeated exposure to sufficiently similar events (consisting of content and context): The events are stored individually, but also accumulate in a separate trace we call knowledge (containing accumulated content and context). When any event later occurs, it consists of stimuli and context. The stimuli get processed by access to knowledge based on similarity of test probe to traces in knowledge-- the features in the knowledge trace gradually are perceived and are placed in short-term memory as a continually changing and growing probe. This probe in turn is used to retrieve additional information in knowledge, and also information from similar event traces. The model, termed SARKAE, specifies the time course of these interacting processes, and shows how they explain perception, knowledge retrieval, event retrieval and retrieval of associations of both types, modeling in detail both accuracy and response time data.

The second project is represented by the thesis of my PhD student, Greg Cox, and by our earlier paper Cox, G. E., & Shiffrin, R. M. (2012). Criterion setting and the dynamics of recognition memory. *Topics in Cognitive Science, 4*(1), 135-150. The thesis is presently in the process of certification at IU (although Greg is now on a ‘postdoctoral’ research appointment at Syracuse University) and is now being prepared for journal submission. This research involved production of a dynamic model for memory storage and particularly retrieval, a model capable of explaining event memory measured by accuracy and response time, and for a variety of tasks including recognition memory, with and without speed stress and speed cutoffs, and memory for associations. Most prior models for event memory that have been used to predict accuracy and response time jointly have dissociated the process of evidence collection and decision making from the processes of perception and memory access. Thus accuracy and response time are the result of a diffusion or random walk that moves at a constant drift rate to one or more response barriers. The present dynamic model changes the rate of evidence collection...
moment by moment as different types of features are extracted from the environment, from our stored knowledge and from event memories. The model explains previously known but largely ignored results, and new results collected in our laboratory, concerning the effects of priming, word frequency in event recognition, effects of speed vs accuracy instructions, the effects of changing test stimuli dynamically over brief periods of time so that the changes are not perceived consciously, the effects seen when the time of response is governed by a signal to respond, the effects of study time, list length and list strength, and the differences between memory for items and the memory for associations between items. The last of these phenomena is based on the idea that item features are collected first and associative features collected later in time. This modeling should represent a major change and advance in the way we understand the processes of memory retrieval.

The third line of research involves empirical studies and modeling of short-term recognition memory, a line of research famously modeled by Saul Sternberg in the 1960s as based on serial exhaustive scanning. Our recent research reveals that the pattern of data originally collected was due to extra time between study of a list of items and the recognition test item, extra time allowing the list items to be rehearsed in various ways. Our research uses a paradigm in which the test item immediately follows the study list: the data pattern changes, and the underlying processes are clarified. The data now show strong effects of lag (recency), and we have used and tested extensively a dynamic model that explains the accuracy and response time data. The results are reported in "Nosofsky, R. M., Cao, R., Cox, G. E., & Shiffrin R. M. (2014a). Familiarity and categorization processes in memory search. Cognitive Psychology, 75, 97-129", and "Nosofsky, R.M., Cox, G.E., Cao, R., & Shiffrin, R.M. (2014b). An exemplar-familiarity model predicts short- term and long-term probe recognition across diverse forms of memory search. Journal of Experimental Psychology: Learning, Memory and Cognition, 40(6), 1524-1539".

The fourth line of research examines memory and precision of memory for attributes of visual stimuli presented simultaneously. A debate has been going on for some time concerning the issue of all-or-none forgetting of the presented visual objects. One class of models proposes all-or-none loss and guessing when the lost item is probed, and another class proposes gradual loss of information for all items in the visual display. Using both accuracy and response time measures, and careful quantitative modeling, we have been able to demonstrate convincingly that all-or-none loss coupled with guessing provides the best account of short-term loss of visual memory. The papers are: "Donkin, C., Nosofsky, R., Gold, J., and Shiffrin, R. M. (2013). Discrete-slots models of visual working-memory response times. Psychological Review, 120(4), 873-902", and "Donkin, C., Nosofsky, R., Gold, J., and Shiffrin, R. M. (2015). Verbal labeling, gradual decay, and sudden death in visual short-term memory. Psychonomic Bulletin and Review, 22, 170-178."

The fifth line of research data concerns statistical learning. Several stimuli (auditory and visual) are presented together on each trial. There is a one to one mapping of sound to vision, but the correct associations on each trial are ambiguous. Over several trials using the same mappings, the correct associations become evident through statistical accumulation. This line of research explores the type of learning we almost always encounter during development, such as the correct word to

The sixth project examines the effects of testing event memory. The basic idea is that tests of items that might or might not have been on a just studied list are also events that are stored in memory. Such storage produces interference by the usual mechanisms of forgetting based on competition/interference. The result is a continuous degradation of event memory performance as testing continues (note that performance decreases for new items that are tested; when a previously tested item is tested again, of course performance increases). We have explored and modeled this effect in several experiments, and the results help explain the processes of forgetting of events. The papers are: "Criss, A. H., Malmberg, K.J., & Shiffrin, R.M. (2011). Output interference in recognition memory testing. Journal of Memory and Language, 64(4), 316-326.", "Malmberg, K. J., Criss, A. H., Gangwani, T. H., & Shiffrin, R. M. (2012). Overcoming the negative consequences of interference that results from recognition memory testing. Psychological Science, 23(2), 115-119.", "Annis, J., Malmberg, K. J., Criss, A. H., and Shiffrin, R. M. (2013). Sources of interference in recognition testing. Journal of Experimental Psychology: Learning, Memory, and Cognition, 39, 1365-1376.", "Malmberg, K.J., Lehman, M., Annis, J., Criss, A.H., & Shiffrin, R.M. (2014). Consequences of testing memory. Psychology of Learning & Motivation - Advances in Research and Theory, 61, 285-313."

The seventh project is aimed to explain seemingly irrational decision making by humans by proposing a new model that assumes humans understanding of probability is based on the rules of quantum probability rather than traditional probability. The most astounding result of those reported was published in PNAS--it tested a prediction derived from the quantum probability model that applies universally and without parameters. The prediction involved the effects of changing the order
of two binary questions asked in succession. The order changes the results, of course, but the quantum theory predicted a particular relation for the changes that no one had previously noticed. Once the prediction was derived we looked back at the roughly 75 national surveys, starting about 1990, carried out by Gallup and Pew that had this manipulation. The prediction held in every such survey (and in two laboratory studies we carried out as an additional test). In addition we note that thus far no one has been able to find a traditional probability theory that can explain these findings, though even should one be found the a priori universal prediction that was confirmed in past data provides a good deal of support for the theory. We also carried out other studies of the quantum theory, and thus far it holds up as a viable account of human understanding of probability and the way that understanding governs decision making. The papers are: "Pothos, E. M., Shiffrin, R. M., & Busemeyer, J. R. (2014). The dynamics of decision making when probabilities are vaguely specified. Journal of Mathematical Psychology, 59, 6-17.", "Wang, Z., Soloway, T., Shiffrin, R. M., & Busmeyer, J. R. (2014). Context effects produced by question orders reveal quantum nature of human judgments. Proceedings of the National Academy of Sciences, 111(26), 9431-9436.", "Busemeyer, J. R., Zheng, W., & Shiffrin, R. M. (2015). Bayesian model comparison favors quantum over standard decision theory account of dynamic inconsistency. Decision, 2, 1-12."

Abstract
There were four major areas of accomplishment, and several important but subsidiary ones. The first two were closely related. The first was represented by the publication in Psychological Review of the paper reporting research supported by the grant, titled: "The co-evolution of knowledge and event memory". The second is represented in the thesis by my PhD student Greg Cox titled: "Dynamic modeling of memory storage and retrieval". This research is now being prepared for submission to Psychological Review. The first represents a general model for the dynamic interaction of event memory and knowledge, based on several studies in which knowledge for novel (Chinese) characters was developed through extensive training. The interaction of this knowledge with event memory was assessed with a knowledge task (pseudo-lexical decision), a perceptual task (perceptual identification), and an episodic recognition task (recognition memory for occurrence of a test item on a studied list). This research represented a major advance because event memory and knowledge memory are usually treated independently. The second major contribution, thus far represented by the thesis and the publications titled "Criterion setting and the dynamics of recognition memory", involved production of a dynamic model for accuracy and response time by which evidence relevant for event memory judgment is collected moment by moment, changing as different features are extracted from the test item and knowledge memory. The results, based both on free response tasks and time limited response tasks, provide important insights into the time course of, and the
effects of, study time, natural language word frequency, list length and strength, associative memory, recognition memory, and recall. The third area of accomplishment is new data supporting development of a new dynamic model of short-term recognition memory explaining lag effects, trial-to-trial effects, list length effects, and use of knowledge, for both accuracy and response time measures. The fourth major area of accomplishment is data and modeling of statistical learning, by which responding correctly concerning the pairings of stimuli becomes increasingly accurate as information is accumulated over trials, although each trial is ambiguous. Other supported research examined recognition decision making based on mouse tracking measurements using Gaussian process regression, the negative effects of testing caused by memory for earlier test items, the dynamics of attention and perception, and several papers supporting a quantum probability model for human decision making.
