Reactions of VX, GD, and HD with Al₂O₃, TiO₂ (anatase and rutile), aluminum, and titanium metal powders have been studied by ²⁷Al, ⁴⁷,⁴⁹Ti, ³¹P, and ¹³C MAS NMR. VX, GD, and HD hydrolyze on both nanosize and conventional Al₂O₃. A significant droplet size effect on the reaction kinetics is observed. For VX and GD, ²⁷Al and ³¹P MAS NMR detect the formation of aluminum phosphonate complexes. Similarly, GD hydrolysis on TiO₂ yields titanium phosphonate species as detected by ³¹P MAS NMR. Attempts at obtaining ⁴⁷,⁴⁹Ti NMR spectra of these species and those of titanium phosphonate model compounds at 14 T were marginally successful. ⁴⁷,⁴⁹Ti NMR spectra were obtainable for anatase and titanium metal; thus, severe second-order quadrupolar linebroadening is suspected for the titanium phosphonate complexes. ⁴⁷,⁴⁹Ti NMR spectra obtained for anatase at high magnetic field (17.5 and 21 T) showed anticipated improvement in peak width and resolution. GD reacted with aluminum and titanium powder in the presence of water results in acid-dissolution of the metals and the formation of their respective metal phosphonates.

**Introduction**

Inorganic oxides are currently being considered as reactive sorbents for the decontamination of chemical warfare agents (CWA). Indeed, an aluminum oxide-based sorbent has already been fielded for use on vehicles and soldiers’ personal equipment. Another, potential application of reactive sorbents is in aircraft filtration systems to provide protection to occupants in contaminated environments. Besides metal oxides, the interaction of CWA with metals is also a concern in the demilitarization of bulk CWA and CWA munitions, as many chemical neutralization and/or natural degradation products are acidic and extremely corrosive to processing equipment. Finally, the identification of stable, metal-derived CWA byproducts is of potential importance to the Chemical Weapons Convention Treaty, where such materials may be uncovered during challenge inspections.

Previous work with nanosize aluminum oxide (AP-Al₂O₃) assessed the reactions of GB (isopropyl methylphosphonofluoridate), GD (pinacolyl methylphosphonofluoridate), HD [bis-(2-chloroethyl) sulfide], and VX [O-ethyl S-(2-disopropylamino)ethyl methylphosphonothioate], where it was found that the products of the nerve agents GB, GD, and VX formed novel aluminophosphonate compounds. Also, appropriate aluminophosphonate “markers” possessing potential environmental stability were identified for each of these nerve agents. In the current study, conventional aluminum oxide (γ-Al₂O₃) is examined and compared to the previous AP-Al₂O₃ results. Also described are preliminary assessments of GD reactions with titanium oxide and titanium metal.

**Experimental Section**

**Materials.** The γ-alumina used is Selexsorb CDX (Alcoa) and has a surface area of 400 m²/g. The alumina was used as received. Anatase, rutile, aluminum, and titania metal powders, titanium(IV) isopropoxide, and pinacolyl methylphosphonate were all obtained from Aldrich. ¹³C-labeled HD (HD*), obtained locally, was employed to enhance sensitivity for ¹³C NMR experiments.

**Titanophosphonate Synthesis.** Titanophosphonate synthesis was adapted from Mutin et al. using titanium(IV) isopropoxide (TIP) and pinacolyl methylphosphonate (PMPA). Typically, a measured molar-amount of PMPA was predissolved in dried CH₃CN (mol-sieves), to which was added a measured, molar-amount of TIP with stirring. ¹H and ³¹P NMR were employed to determine the extent of reaction of TIP and PMPA, respectively, to form titanophosphonate species. In particular, it was found that a 1:2 molar ratio of TIP:PMPA gave an immediate white precipitate of compound with complete reaction/complexation of TIP and PMPA. Recrystallization of this material with alcohol provided light-yellow, clear crystals which were apparently amorphous as they did not diffract X-rays. Calculated for C₁₂H₂₆O₇P₂Ti: C, 36.8; H, 6.7; P, 15.8; Ti, 12.2. Found: C, 35.90; H, 7.19; P, 11.67; Ti, 13.39.

**NMR.** ²⁷Al, ³¹P, and ¹³C MAS NMR spectra were obtained at 7 T with a Varian Unityplus 300 NMR spectrometer equipped with a Doty Scientific 7 mm high-speed VT-MAS probe. ⁴⁷,⁴⁹Ti MAS NMR spectra were obtained at 14, 17.5, and 21 T with Varian INOVA 600 and Bruker AVANCE 750 and 900 NMR spectrometers, respectively, using spin echo pulse sequences to minimize “ringing”. The 14 and 17.5 T instruments were equipped with Doty Scientific 5 mm XC MAS NMR probes, and the 21 T instrument was equipped with a Bruker 3.2 mm MAS NMR probe. Double O-ring caps were used to seal 7 mm
Dramatic effects of surface hydration on HD reaction kinetics are due to surface-bound PMPA (31P) and tetrahedral (3T) sites of γ-Al2O3 (see text).

Reaction Procedure. Caution. These experiments should only be performed by trained personnel using applicable safety procedures. In a typical kinetic run with γ-Al2O3, single 3.5-μL drops (ca. 1.5 wt %) or larger 13-μL drops (ca. 5 wt %) of neat liquid agent were added via syringe to the center of a column contained in a 7 mm MAS NMR rotor. The rotor was then sealed with a double O-ring cap. MAS NMR spectra were obtained periodically to monitor the reaction in situ. For the very high loadings of GD examined on titania, titanium, and aluminum metal, the agent was either mixed with the material prior to NMR analysis or allowed to settle onto a short column of the material contained in a 5 mm NMR tube. The tube was then capped, sealed with Parafilm, and placed within the NMR spectrometer such that the entire column of material/sorbed agent was contained within the NMR detector-coil region. This latter procedure similarly allowed in situ NMR monitoring of reactions with these solid materials using “solution” NMR conditions.

Results and Discussion

Conventional vs Nanosize Aluminum Oxide Reactions. Figures 1–3 show MAS NMR spectra obtained for GD, VX, and HD reacted with conventional γ-Al2O3, showing the effect of droplet size on reaction rate. Corresponding reaction profiles are shown in Figure 4. For comparison, previous data3 is also shown for GD, VX, and HD on nanosize AP-Al2O3.

For GD, an identical rate (t1/2 = 1.8 h) with varying drop size (3 or 16-μL) is observed for γ-Al2O3 and AP-Al2O3. The expected3 GD-derived aluminophosphonate (Al[O2P(CH3)OPh]), 1) is also clearly evident in both the 31P MAS and 27Al CP-MAS NMR spectra as indicated in Figure 1. Other peaks are due to surface-bound PMPA (3T) and tetrahedral (3T) and octahedral (3O) Al sites γ-Al2O3 (27Al).6

As depicted in Figure 1, the Al site for compound 1 is envisioned to possess O₆ symmetry owing to the proximity of its 27Al MAS NMR peak to that of the O₆ peak6 for γ-Al2O3. The ability to adequately resolve these two, distinct O₆ sites is due to two, main favorable factors that lead to reduced second-order quadrupole effects.7,8 The first is that, even though 27Al is quadrupolar, it possesses a modest quadrupole moment, Q (Table 1), meaning that it will only modestly couple with nonzero electric field gradients, eq.8 Second, symmetric environments such as O₆ and the like, even though perhaps slightly perturbed, provide for a nearly zero electric field gradient and, hence, a nearly zero quadrupole coupling constant, Qeq = e2Qq/h. Thus, even at a modest field of 7.0 T, relatively narrow NMR linewidths and adequate resolution of various 27Al sites is possible for alumina/aluminophosphate mixtures. Unfortunately, as will be seen below, conditions are not quite so favorable for various 47,48Ti sites in titanias/titanophosphonate mixtures.

Regarding the reaction profiles for VX in Figure 4, there is some dependence of the steady-state reaction rate on droplet size as the 3.5-μL droplets possess nearly identical half-lives on both γ-Al2O3 and AP-Al2O3, t1/2 = 6.8 and 6.4 days, respectively, yet the larger 15-μL droplet size on γ-Al2O3 yields t1/2 = 9.2 days.

Analogous to the GD reaction, the VX-derived aluminophosphonate (Al[O2P(CH3)OPh]3) 2) forms as indicated in the 31P MAS NMR spectra of Figure 2. Further note the sharpness of the 31P MAS NMR peak for this species, which remains soluble near neutral pH, in comparison to that of 1 which is insoluble at neutral pH. Thus, the sharpness of the peak for 2 is attributed to increased motion as a result of this species remaining dissolved within the adsorbed water layer residing on the as-received (un-dried) γ-Al2O3.

For HD, the dependence of steady-state reaction rate on droplet size is quite extreme, with the 13-μL droplet size exhibiting t1/2 = 70.9 h, compared to 44 min for the 3.5-μL droplet. For the small 3.5-μL droplet size, the reaction on γ-Al2O3 is considerably faster than that on AP-Al2O3 (t1/2 = 6.3 h). However, the surface hydration state, which was not controlled, may be contributing substantially to this difference. Dramatic effects of surface hydration on HD reaction kinetics on sorbents have been previously observed.9 Indeed, substantial formation of the CH-TG sulfonium ion3 on γ-Al2O3 indicates
abundant water is present; alternatively, the preferred thiodiglycol (TG) product observed for AP-Al$_2$O$_3$ is suggestive of a much drier surface. Additional studies looking at hydration effects must be conducted to definitively compare the relative reactivities of the two aluminas.

The reactivity behavior exhibited by the agents, which is drop size-dependent in some cases, may be attributed to three major effects: (1) smaller drops react faster owing to their large surface to volume ratio; (2) the vapor pressure of the agents varies widely,$^{10}$ with GD > HD ≫ VX, allowing the more volatile agents to spread more rapidly through the sorbent (in lieu of other transport mechanisms such as water-solubility); and (3) the order of water solubility of the agents, under basic conditions, is GD > VX ≫ HD. Thus, with its solubility in water, GD is able to spread and react more quickly across the hydrated alumina surface and drop size has little effect; the high volatility of GD also contributes to its ability to quickly disperse and react. However, VX has more limited water solubility (under basic conditions; $^{1}$ $pK_a = 8.6^{11}$) and extremely low volatility; thus, it spreads more slowly, even on a (basic) hydrated surface, resulting in a noticeable drop-size effect, and it is by far the most persistent. Finally, although HD is water-insoluble, its volatility and rather facile hydrolysis$^{1}$ still enables it react quite

fast in small drops but much more slowly in large drops. Additionally, surface hydration has been shown to have a profound impact on the reaction of HD\(^+\) (as well as the other agents; see below for GD), and future studies are needed to sort this out. Indeed, such uncontrolled hydration effects could well account for the apparent reactivity differences exhibited by \(\gamma\)-Al\(_2\)O\(_3\) and AP-Al\(_2\)O\(_3\) in the small, 3.5-\(\mu\)L drop-size experiments for HD.

**GD Reaction With Al Metal.** As mentioned above, nerve agent degradation generates acidic products which have been shown\(^3\) to dissolve alumina to generate aluminophosphonates. Such acids would also be expected to oxidize/corrode aluminum metal (Al\(_{\text{m}}\)) to generate the same products. The reaction of GD with Al\(_{\text{m}}\) powder in the presence of water does result in the quantitative formation of \(1\), a white, microcrystalline powder (Figure 5). Note that a single \(^{31}\)P MAS NMR peak is present for the compound indicative of the simple crystal structure containing only a single P site. The \(^{13}\)C MAS NMR spectrum yields additional important information on the structure, showing that the pinacolyl group is still attached to the phosphonate; that is, secondary hydrolysis of this group did not occur. Finally, the \(^{27}\)Al MAS NMR spectrum shows residual Al\(_{\text{m}}\) at the expected Knight shift of 1640 ppm.\(^{12}\) Note that this metal has cubic symmetry and, hence, an essentially zero \(Q_{cc}\), leading to its quite narrow NMR line width.

**Titanium Oxide Reactions.** Titanium oxide exists in two common forms, rutile and anatase.\(^{13}\) Initial work focused on their relative reactivities for GD and the potential formation of titanophosphonates.\(^4\) Figure 6 shows \(^{31}\)P NMR spectra obtained for 50 wt % GD on anatase (loaded with 11 wt % water) and rutile (initially without added water). In the absence of added water, GD reacts only slowly on rutile; however, the addition of copious water (100 wt %) results in the facile, quantitative reaction to the expected hydrolysis product PMPA. For GD on anatase with preadsorbed water, a rather facile reaction similarly ensues, again providing quantitative conversion to PMPA. Thus, both anatase and rutile react with GD, provided adequate water is present.

Closer inspection of the GD-anatase product by \(^{31}\)P MAS NMR (Figure 6), which enabled improved resolution, revealed additional, small peaks due to titanophosphonate species, at least some of which are soluble as shown in the \(^{31}\)P NMR spectrum of the CH\(_3\)CN extract of the product(s) (Figure 6). The large peak in the extract is free PMPA; the small peaks are due to PMPA complexed in one or more titanophosphonate species. Unlike the corresponding aluminophosphonate, the titanophosphonate(s) must possess a more complex structure as evidenced by the multiple P sites.

As shown in Figure 7, attempts at synthesizing\(^4\) the authentic titanophosphonate(s) starting with Ti(OPr\(_i\))\(_4\) (TIP) and PMPA showed that a mole ratio of about one Ti\(^{4+}\) to four PMPA gave a soluble complex possessing multiple P sites (a minor amount of free PMPA is also detected). However, a mole ratio of one Ti\(^{4+}\) to two PMPA gave an immediate white precipitate of \(3\) with no free PMPA. \(^{31}\)P MAS NMR showed the presence of multiple P sites for \(3\).\(^{13}\)C MAS NMR confirmed that the PMPA remained intact in the complex (no hydrolysis of the pinacolyl group occurred). An attempt at obtaining a \(^{47,49}\)Ti NMR spectrum of the compound yielded only a single, broad feature at \(-512\) ppm. Such a broad peak suggests that the Ti sites possess distorted symmetry and, hence, a large \(Q_{cc}\).

**GD Reaction With Ti Metal.** Figure 8 shows NMR spectra obtained for the reaction for GD with titanium metal powder (Ti\(_{\text{m}}\)). For this sample, Ti\(_{\text{m}}\) (0.1 g, 2.1 mmol) was mixed with anatase (0.3 g, 3.8 mmol) and reacted with 193 wt % GD (0.77 mL, 4.2 mmol). \(^{31}\)P NMR of the precipitate in contact with the reaction solution (Figure 8) showed the formation of the
titanophosphonate species with very little free PMPA (sharp peak). Ti NMR spectra taken before and after the addition of GD show the loss of the Ti (m) peak (at the expected Knight shift of ca. 2800 ppm) and the formation of the titanophosphonate feature at -547 ppm. The anatase peak at -862 ppm also exhibited a substantial decrease, showing that GD reacted with this material as well. Note that Ti (m) possesses lower, hexagonal symmetry leading to a rather large Q of 9.25 MHz and the resultant broadened line shape. By comparison, anatase possesses tetragonal symmetry leading to distorted O sites but a more modest Q of 4.79 MHz and a much narrower line width. Note that for these low signal-to-noise spectra, only the 47 Ti line is observed which is much sharper than the 49 Ti line (see below) owing to its lower Q and larger spin.

Nature of the GD-Derived Titanophosphonate Structure. Titanophosphonates are well-known in the literature, many of which are soluble. All exhibit quite complex, cage-like structures, possessing multiple Ti and/or P sites. Furthermore, frequently the Ti sites are not symmetric. Thus, it is not surprising that the structure of the GD-derived titanophosphonate is also complex, possessing multiple P sites (as shown by 31 P NMR) and that the Ti sites have apparent distorted symmetries (as suggested by 47,49 Ti NMR). During synthesis from titanium alkoxides such as TIP, titanophosphonates tend to form Ti-O-Ti bonds in addition to Ti-O-P bonds. This is due to a side reaction with adventitious water. Indeed, greater yields of titanophosphonates are seen with the addition of water.

Figure 7. 31 P and 1H solution NMR, 47,49 Ti static NMR, and 31 P and 13 C MAS NMR spectra obtained at 7.0 T and 14 T for titanophosphonate syntheses. Insets show PMPA:TIP ratios employed and peaks due to soluble titanophosphonate(s), free PMPA, and insoluble titanophosphonate (see text).

Figure 8. 31 P solution NMR spectrum obtained for GD reacted with TIP (left) and 47,49 Ti static NMR spectra obtained at 14 T for the reaction of GD with TIP mixed with anatase (right column): TIP mixed with anatase before (middle right) and after GD added (bottom right). Also shown is the 47,49 Ti static NMR spectrum of authentic synthesized from 2:1 reaction of PMPA and TIP (top, right). Insets show reactions involved and peak assignments for titanophosphonate 3, TIP, and anatase (see text).
Thus, insoluble, 1:2 TIP:PMPA titanophosphonate 3 is postulated to have the following empirical formula: Ti(O)(O2P(CH3)OPin)2. Note that elemental analysis of the compound is consistent with this formula (see the Experimental Section).

47,49 Ti NMR at High Magnetic Field. The attempts to obtain decent 47,49 Ti NMR spectra of titanophosphonates at the modest field of 14 T, which was intended to both garner structural information analogous to that provided by the 27Al NMR spectra obtained for the aluminophosphonates (at a quite modest field of 7 T) and to provide for the in situ detection of these species within solid matrices, were only marginally successful. A major source of the difficulty apparently lies in the rather large Q’s of the 47Ti and 49Ti nuclei, 0.29 and 0.24, respectively (Table 1). Both of these Q values are considerably larger than that of 27Al (0.15). As mentioned earlier, large Q values lead to strong coupling to nonzero electric field gradients, eq, induced by distorted site symmetries giving rise to large quadrupole coupling constants, e2Q/\hbar. Thus, the resultant large, second-order quadrupolar effects yield broadened lines and poor resolution of potential multiple site resonances. Indeed, it is precisely the severely distorted site symmetry suspected for the more complex titanophosphonates (see above) that appears to be particularly problematic since adequate spectra could be obtained for both Ti(m) and anatase which possess modest symmetry perturbations (Q’s of 9.25 and 4.79 MHz, respectively) (Table 1). Therefore, it is anticipated that 3 possesses a significantly larger Qec. Fortunately, such second-order quadrupolar effects become less important and are relatively minimized at higher magnetic fields, thus providing for relatively narrower lines and improved resolution. To investigate the potential advantage of obtaining 47,49 Ti NMR spectra at higher magnetic fields, spectra of anatase were obtained at 17.5 and 21 T for comparison with results at 14 T. These spectra are shown in Figure 9.

The spectrum obtained at 14 T (bottom of Figure 9) shows a rather sharp, doublet-like pattern for the 49Ti nuclide centered at about −950 ppm and a much broader feature for the 47Ti nuclide centered at −1350 ppm. Although both nuclides are experiencing the same distorted O8 site symmetry and attendant nonzero electric field gradient, eq, the 49Ti nuclide exhibits more severe second-order quadrupole effects owing to both its larger Q (0.29 vs 0.24 for 49Ti) and smaller spin (I = 5/2 vs 7/2 for 49Ti). Thus, these seemingly subtle differences combine to make a dramatic impact on line width and resolution. At the higher magnetic fields, the expected line-narrowing and improved resolution is realized owing to the increasing dominance of the magnetic Zeeman interaction compared to that of the magnetic field-independent quadrupolar interaction (the 21 T spectrum does not possess adequate signal-to-noise to reveal the 49Ti resonance). Further note that the centers of the 49Ti and 49Ti features shift toward higher frequency at the higher fields since these line shapes are actually MAS-averaged second-order quadrupolar powder patterns and, thus, do not truly represent isotropic chemical shifts.

Conclusions

Drop size has a large effect on the reaction of VX and HD with alumina but less effect on the reaction of GD. This is attributed to the band the greater water solubility and volatility of GD, which allows it to spread more readily over the hydrated alumina surface. GD reacts with Al(m) to form the same aluminophosphonate 1 derived from alumina. GD reacts with rutile, anatase, and Ti(m) to yield titanophosphonates. The formula of the insoluble GD-derived titanophosphonate 3 is postulated to be Ti(O)(O2P(CH3)OPin)2, in agreement with elemental analysis. High-field 47,49 Ti MAS NMR of anatase shows marked narrowing of its signals compared to low-field measurements. High-field 47,49 Ti MAS NMR should similarly allow for improved characterization of agent-derived titanophosphonates.
