SYSTEM AND METHOD FOR STOCHASTIC CHARACTERIZATION
OF SPARSE, FOUR-DIMENSIONAL, UNDERWATER-SOUND SIGNALS

STATEMENT OF GOVERNMENT INTEREST
The invention described herein may be manufactured and used
by or for the Government of the United States of America for
governmental purposes without the payment of any royalties
thereon or therefor.

CROSS REFERENCE TO RELATED APPLICATION
The instant application is related to commonly assigned U.S.
Patent Applications entitled SYSTEM AND APPARATUS FOR THE
DETECTION OF RANDOMNESS IN TIME SERIES DISTRIBUTIONS MADE UP OF
SPARSE DATA SETS, Serial No. 09/379,210, filed 20 August 1999
(Attorney Docket No. 78645) and SYSTEM AND APPARATUS FOR
STOCHASTIC RANDOMNESS DETECTION OF WHITE NOISE IN THREE
DIMENSIONAL TIME SERIES DISTRIBUTIONS, Serial No. 09/678,877,

BACKGROUND OF THE INVENTION
(1) Field of the Invention
The invention relates generally to the field of systems and
methods for performing digital signal processing operations in
connection with signals and more particularly to systems and
methods for characterizing signals to determine their stochastic
properties, that is, to determine whether they are random. More particularly it relates to a system for performing this function of characterizing signals that represent information on small samples, which in turn is representable as a composite of four component items of mutually orthogonal measurement information. If the signals are random, they may be determined to constitute noise, in which case additional signal processing efforts which might be undertaken to process the signals to extract information therefrom can be avoided. Stated another way, the system and method allows a determination to be made of the extent to which a pattern of data items, or sample points representing four dimensions of measurement information conforms to a random structure of data.

(2) Description of the Prior Art

In a number of applications in which four mutually orthogonal items of measurement information undergo processing, it is desirable to be able to determine the likelihood that a signal is random. For example, an acoustic signal, received in an ocean environment, may constitute noise alone, or it may include some useful "information" along with a background noise. If the signal constitutes noise alone, its amplitude will be random, but if it includes information it will not be random and further processing may be useful to identify the information. In some prior art signal processing systems, it is assumed that four mutually orthogonal items of useful measurement information are present in the signal, and the signal is processed to try to extract this intelligence. It may be the case that the noise
level of a received signal is so great that the information
cannot be extracted and the processing effort will be wasted in
any event. It is accordingly desirable to be able to determine
the likelihood that a signal constitutes only noise, or if it
also includes four mutually orthogonal items of measurement
information so that a determination can be made as to whether
processing of the signal to extract the information would be
useful, particularly when such four-dimensional data are sparse
in quantity, i.e., a small sample of measurements are available
for processing the signal.

The availability of four dimensional tracking systems,
comprising the processing of three sensor-based measurements and
time as a fourth dimension, is well known to those skilled in the
art. One such reference, hereby incorporated in its entirety, is
the technical paper "Three-Dimensional Tracking Using On-Board
Measurements," C.M. Rekkas, et al., IEEE TRANSACTIONS ON AEROSPACE

A commonly assigned herewith U.S. Patent No. 5,963,591
issued 5 October 1999 discloses a system and method to
characterize whether randomness is present in signal samples
representable as a composite of four embedded orthogonal signal
data items. One illustrative use of such a system and method is
in processing underwater sound signals in connection with
submarine undersea warfare, in order to spatially localize the
source of emitted sound signals from a sonar contact received by
a submarines towed sonar array. As a practical matter there are
a number of conditions which cause data spareness, including:
(i) Extremely low data-rate (20-sec/datum in most underwater naval applications);
(ii) Naval tactical strategies require rapid maneuvering, thus data is lost in transitions;
(iii) Measurements corrupted by environmental background noise and other interferences;
(iv) Transient behaviors of underwater signals (launch signatures, sonar frequency, etc); and
(v) Imperfection in physical devices.

There are a significant number of practical situations where it is desirable to process collections of signal data too sparse to yield a determination of whether or not the signal is solely random noise by the "nearest neighbor" methodology of processing taught by U.S. 5,963,591. Accordingly, there has been a continuing need to provide a system and method having improved capability for characterizing whether randomness is present in sparse accumulations of signals which are composited of four orthogonally related signal data items. Other prior art patents addressing systems and methods for characterizing whether randomness is present in data samples includes U.S. Patent 5,966,414 issued 12 October 1999, and U.S. Patent 5,703,906 issued 30 December 1997. (These are commonly assigned herewith also). However, none provide the teachings to address this need for characterization of presence of randomness with embedded four orthogonally related data items under conditions of sparseness of date. Likewise, an article which the inventors hereof co-authored with another co-author "Novel Method for Characterizing
Stochastic Processes and Its Application in the Undersea Environment", Proceedings of the 6th International Conference on Signal Processing Applications and Technology, June 1995 does not contain disclosure of teachings to address this need.

SUMMARY OF THE INVENTION

It is therefore an object of the invention to provide a new and improved signal processing system for processing signals which may contain useful information comprised of four mutually orthogonal items of measurement information to determine the stochastic (random) properties of the signals based on small (sparse) data.

As a brief summary, the signal processing system processes a digital signal, generated in response to an analog signal which includes a noise component and possibly also another component consisting of four mutually orthogonal items of measurement information. An information processing sub-system receives the digital signal and processes it to extract the information component. A noise likelihood determination sub-system receives the digital signal and generates a random noise assessment indicative of whether the digital signal comprises solely random noise, and also a degree-of-randomness assessment indicative of the degree to which the digital signal comprises solely random noise. The operation of the information processing sub-system is controlled in response one or both of these assessments. The information processing system is illustrated as combat control equipment for submarine warfare, which utilizes a sonar signal
input produced by a towed linear transducer array, and whose mode of operation employs four mutually orthogonal items of measurement information comprising: (i) clock time associated with the interval of time over which the sample point measurements are taken, (ii) conical angle representing bearing of a passive sonar contact derived from the signal produced by the towed array, (iii) a frequency characteristic of the sonar signal and (iv) a measurement of the signal-to-noise ratio (SNR) of the sonar signal.

BRIEF DESCRIPTION OF THE DRAWINGS

This invention is pointed out with particularity in the appended claims. The above and further advantages of this invention may be better understood by referring to the following description taken in conjunction with the accompanying drawings, in which:

FIG. 1 is a functional block diagram of an organization for processing a signal which may contain information comprised of four items of mutually orthogonal measurement information, constructed in accordance with the invention;

FIGS. 2A and 2B together comprise a flow chart depicting the operations of the system depicted in FIG. 1; and

FIG. 3 is a perspective view diagrammatically representing a succession of non-overlapping, three-dimensional sample regions symbolically depicted as cubical volumes each partitioned into cubical subvolumes, each containing a population of sample point measurements, correlated with the clock time associated with the
interval of time over which the sample point measurements are taken, constituting the fourth dimension information component. The cubes in FIG. 3 have been sliced up into smaller cubes to diagrammatically highlight the new and useful improvement of the system and method. It will be appreciated that this figure is diagrammatic because represents a four-dimensional cube that is not capable of true pictorial representation.

DESCRIPTION OF THE PREFERRED EMBODIMENT

The invention provides a signal processing system 10 including a noise likelihood determination sub-system 11 constructed in accordance with the invention. FIG. 1 is a functional block diagram of the signal processing system 10. With reference to FIG. 1, the signal processing system 10 includes, in addition to the noise likelihood determination sub-system 11, an input sub-system 12, an information processing sub-system 13 and an output 14. Input sub-system 12 includes one or more analog transducers, and performs a front end processing function that provides a digital output signal which represents four mutually orthogonal items of measurement information. The transducer receives the signal, which is in acoustic, electrical, electromagnetic or other form and converts it to preferably digital form for processing. For example, sub-system 12 may be embodied as sonar array transducer equipment including a front end processing stage for feeding digital data to a sub-system 13 embodied as a combat control equipment for a naval submarine. The signal provided by sub-system 12 may be a multiplexed signal
representing four-dimensions of measurement information related
to a passive sonar acoustic signal which emanates from a sonar
contact and which is received by one or more analog transducer
arrays, including a linear transducer array towed behind the
submarine. Such input subsystem 12 may process the received
acoustic signal to provide a multiplexed digital output of items
of data (sometimes hereinafter and in the appended claims
referred to as "sample points" or simply "points") comprised of a
signal components representative of (i) clock-times associated
with the intervals of time during which the measurement samples
are generated, (ii) signal power in a sector of conical angle
representing bearing of the contact, (iii) signal power in a
sector or "frequency bin" of the spectral density distribution
function of the acoustic signal and (iv) signal to noise ratio
(SNR). The information processing sub-system 13 performs
conventional signal processing operations, such as adaptive and
other filtering, to extract this information component from the
digital signal. In accordance with the invention, the noise
likelihood determination sub-system 11 determines the likelihood
that the signal is solely noise, and also provides an assessment
of the degree to which the incoming signal is composed of noise.
This information will determine whether sub-system 13 will
provide a useful result.

The operations performed by the noise likelihood
determination sub-system 11 will be described in connection with
the flowcharts in FIGS. 2A and 2B. Generally, the noise
likelihood determination sub-system 11 performs several tests in
connection with digital signal sample points. Each digital
signal sample point, or simply "point", within each population
comprises one of a series of composite digital signals, with each
composite signal containing components representing four mutually
orthogonal items of measurement information. For example, the
sample point may be in the form of a multiplexed message
containing four components, each representing one of the
measurement information items. Each sample point is generated in
a symbolic four-dimensional aperture defined, for example, by a
selected repetitive interval of time. In turn, each signal
sample point is one of a series of such points in a selected
population of "N" points. In the aforesaid example in which sub-
system 13 is embodied as submarine combat control equipment, the
characteristic of mutual orthogonality of the four items of
measurement information is an inherent characteristic rooted in
the nature of the fire control or contact tracking problems being
solved by sub-systems 12 and 13. The series of spatial apertures
used in generating the various populations may be overlapping or
non-overlapping. FIG. 3 is a perspective view in which the
round, black dots diagrammatically represents a sequence of
digital data points, each representing a signal sample point
taken at successive intervals in time. The "t" axis (which in
the perspective view of FIG. 3 is the bottom horizontal axis)
represents clock time and the location of a black dot relative
thereeto represents the time of occurrence of a spatial aperture.
More particularly, it is a Cartesian representation of the
instant of clock time of occurrence of some event (such as end
time) of the interval of time which generates the spatial
aperture. Clock time constitutes one of four mutually orthogonal
items of measurement information diagrammatical depicted in FIG.
3. The "x" axis (horizontal axis in the perspective view)
provides a Cartesian representation of the relationship of a
another of the four mutually orthogonal items of measurement
information. The "y" axis (axis perpendicular to the plane of
the "t" and "x" axis in the perspective view) provides a
Cartesian representation of a third of four mutually orthogonal
items of measurement information, and z, which is perpendicular
to the t-x-y hyperplane, provides a Cartesian representation of a
fourth of the four mutually orthogonal items of measurement
information. Successive populations of "N" signal sample points
data are represented by successive cubical volumes
(diagrammatically indicated in FIG. 3), or regions, of symbolic
four-dimensional space.

With reference again to the flow charts of FIGS. 2A and 2B,
the noise likelihood determination sub-system 11 will initially
record the digital values represented by the various sample
points, such as shown in FIG. 3, for analysis (step 100) and
identify the number of populations of sample points to be
analyzed (step 101).

The noise likelihood determination sub-system 11 then
proceeds to a series of iterations, in each iteration selecting
one sample point population and generating several metrics useful
in determining the likelihood that the sample points in the
population are randomly distributed in a four-dimensional spatial
region containing the sample, that is, in the portion of the
Cartesian space illustrated in FIG. 3 as a t-x-y-z symbolic
cubical volume containing a population, or set, of "N" of sample
points. It will be appreciated that the region (cubical volume
in FIG. 3) containing each population of "N" sample points is
bounded (step 102) along the time axis (that is, the "t" -or
bottom horizontal-axis shown in FIG. 3) by the beginning and end
clock times for the region, and along each of the other three
axes representing different ones of the mutually orthogonal items
of measurement information (that is: the "x" -or horizontal-
axis; and the "y" -or perpendicular to "t-x" plane- axis;) and
"z" axis -perpendicular to all other axes- by minimum and maximum
magnitudes of measurement values chosen to be inclusive of all
sample points.

In each iteration, after selecting the sample point
population to be analyzed during the iteration, the noise
likelihood determination sub-system 11 then determines the best
manner in which to partition the regions into subspace regions
comprising a number k of subspaces each a cube in shape and of a
determinable volume in 4-D hyperspace (step 103). The number of
such subspaces that has at least one distribution point is then
determined (step 104). The noise likelihood determination sub-
system 11 in step 103 generates the number of partitions that are
expected to be nonempty if the distribution of measurements
behaves in a random manner, such a determination having been
derived from the classical Poisson method introducing "k" to
provide the number of subregion of the total region appropriate
for small sample data processing, as

\[ E(M) = k(1-e^{-k}) \]  

(1)

Stated another way "E(M)" is the expected number of occupied boxes in a Poisson random distribute where E(M) represent "Expected Number," M is the actual number of subspace boxes (cubes) in 4-space nonempty across all subspace boxes in 4-D hyperspace, e is the mathematical constant 2.71828..., and k is the total number of subspace cubes into which the total four-dimensional cube has been sliced.

It can be appreciated that the quantity in Eq(1) must be determined for a given dimensional cardinality, namely four. Thus to express the mathematical formula for determining the number of partitions required for optimum performance, the quantity k is determined as:

\[ k = \begin{cases} 
  k_i & \text{if} \quad |N - k_i| \leq |N - k_2| \\
  k_2 & \text{otherwise}
\end{cases} \]  

(2)

\[ k_i = \left[ \text{int}(N^{1/4}) \right]^4 \]

\[ k_2 = \left[ \text{int}(N^{1/4}) + 1 \right]^4 \]

where "int" is the operator specifying the integer part only of a calculation.

The noise likelihood determination sub-system 11 in step 104 generates the actual number of partitions nonempty, M, as follows. An exhaustive search is made across the k subspaces, maintaining a tally of the number of partitions nonempty, and this tally is compared to the value in Equation (1) to determine
if the actually tally or partitions nonempty, M, matches the
theoretical value of the number of partitions nonempty, E(M), to
a predetermined statistical tolerance.

Following step 104, the noise likelihood determination sub-
system 11 generates a standard error value \( \sigma_M \) of the number of
partitions expected to be nonempty in a random population as

\[
\sigma_M \sqrt{k \left(1 - e^{-n/k}\right) e^{-n/k}}
\]

where \( k, N, e \) are as hereinabove defined (step 105).

The noise likelihood determination sub-system 11 uses the
values for \( E(M) \) (the average number of partitions nonempty that
would be expected if the distribution were randomly distributed),
\( M \) (the actual number of partitions nonempty), and the error value
\( \sigma_M \) to generate a normal deviation statistic

\[
\frac{M - E(M)}{\sigma_M}
\]

(step 106) which will be used in performing a significance test
as described below in connection with step 108.

Following step 106, the noise likelihood determination sub-
system 11 performs a series of operations to generate a second
randomness identifier R, which it uses in determining the
likelihood that the digital signal represents a random
distribution. Subsystem 11 computes randomness identifier R in
accordance with the relationship

\[
\frac{M}{E(M)}
\]

where the symbols in both the numeratorator and the denominator are
as hereinabove defined. Values of R range from 0 (all points congest onto a single plane), through 1.0 (indicating pure randomness), to about 2.0 (all points are from a uniform distribution of polyhedrons) in four-dimensional symbolic space. As an illustration of the interpretive utility of R, should its value be 0.50, it is deemed in connection with the operation of system 10 that this value represents a condition of the degree-of-randomness of a stream of incoming sample points which is generally 50% random. The usefulness of this degree-of-randomness output will be illustrated later herein in conjunction with an embodiment of information processing sub-system 13 comprising submarine combat control equipment of a type which employs Bayesian-based cost function and multiple hypothesis assessment techniques to enhance effectiveness of low signal-to-noise-rati on signals.

The noise likelihood determination sub-system 11 generates the values for Z (equation (4)), and R (equation (5)) for each of the plurality of populations. Accordingly, after it finishes generating the values (step 109) for one population, it returns to step 103 to perform the operations for the next population (step 107). After performing the operations to generate values for Z, and R for all of the populations, it sequences to a step 108 to perform a conventional significance test. In that operation (step 109) in connection with the value for Z, the noise likelihood determination sub-system 11 uses as the null hypothesis

\[ H_0 : M = E(M) \]
as indicating that the points are randomly distributed, and uses the alternate hypothesis

\[ H_1 : M \neq E(M) \] (7)

as indicating that the points are not randomly distributed. It will be appreciated that, if the points are randomly distributed, the values for M, the average partition nonempty total in the population, would be distributed around \( E(M) \), the average occupancy total that would be expected if the points were randomly distributed, in a Gaussian distribution with a mean, or average, of \( E(M) \). The standard significance test, using values for \( M \), \( E(M) \) and the normal deviate value \( Z \), will indicate the likelihood that the null hypothesis is correct. The noise likelihood determination sub-system 11 may perform similar operations in connection with the values of \( R \) and the uniform dispersion plots generated for all of the populations, and will determine an assessment as to the likelihood that the signal as received by the transducer was totally random and if not determines a degree-of-randomness assessment. Subsystem 11 provides that assessment to the information processing sub-system 13. The information processing sub-system 13 can use the randomness assessment in determining the utility of having an output from information processing system 13 appear at output 14, as will be presently illustrated.

As exemplary embodiment of information processing sub-system 13 comprises submarine combat control equipment which is responsive to passive sonar signals received (i) by a towed linear array trailing behind the submarine, and (ii) by a
spherical transducer array at the submarine's bow. Measurement
information representing clock times at the ends of the time
intervals employed in generating sample points is internally
available in the combat control equipment. Measurement
information representing an actual relationship between the
contact and the towed array (signal power in a conical angle
sector representing conical bearing angle of a sonar contact
relative to the axis of the towed array) is gathered by the towed
array. Measurement information representing a frequency
characteristic (signal power in a sector of the signal's spectral
frequency distribution function) may be gathered by either the
spherical array or the towed array or both. A SNR measurement is
gathered by the spherical array. The combat control equipment is
of a type which employs Bayesian-based statistical cost function
techniques and multiple hypothesis assessment techniques to
enable the equipment to generate analytical solutions of contact
state estimations of the location of the contact. The principles
of both Bayesian-based cost function techniques and multiple
hypotheses assessment techniques are conventional and well known.
Using these techniques, meaningful statistical state estimates of
a contact's location can be determined from signals as noisy as
having a 50% degree-of-randomness (R=0.5). The fact that the
submarine's sonar signal gathering equipment provides four
mutually orthogonal items of information measurements, namely (i)
conical angle of the contact, (ii) a frequency characteristic of
the sonar signal, (iii) a clock time having a predetermined timed
relationship to each time interval over which the signal is
sampled, and (iv) SNR enables the combat system equipment to
determine whether the processing performable by sub-system 13
should be available at output 14. For example, based upon a
premise that sub-system can provide information yielding a
meaningful state estimation of a contact's location with an input
signal as noisy as having a degree of randomness R=0.5, but no
higher, system 10 is provided with a suitable control to prevent
appearance of any signal at output 14 if: (i) the signal from
input sub-system 12 results in a "null hypothesis" determination
(equation (6)), i.e., the input signal is essentially solely
random noise; or (ii) the signal results in an "alternate
hypothesis (equation (7)) determination, but sub-system 11
further determines the degree-of-randomness, R, of the signal
from input sub-system is a value greater than 0.5. The control
can prevent appearance of a signal at output 14 by any suitable
mode such as blocking coupling from input sub-system 12 to sub-
system 13, disabling sub-system 13, or blocking coupling from the
output of sub-system 13 to output 14.

Although the noise likelihood determination sub-system 11
has been described in connection with assessing randomness in
connection with a signal, such as an acoustic, electrical or
electromagnetic signal, it will be appreciated that the sub-
system 11 will find utility in other areas in which it is
desirable to assess randomness. Also, although described in
relation to a Cartesian coordinate system, sub-system 11 will
also find utility in embodiments that employ a spherical
coordinate system, or other coordinate systems.
The preceding description has been limited to a specific embodiment of this invention and the variations just discussed. It will be apparent, however, that even other variations and modifications may be made to the invention, with the attainment of some or all of the advantages of the invention. Therefore, it is the object to cover all such variations and modifications as come within the true spirit and scope of the invention.
SYSTEM AND METHOD FOR STOCHASTIC CHARACTERIZATION OF
SPARSE, FOUR-DIMENSIONAL, UNDERWATER-SOUND SIGNALS

ABSTRACT OF THE DISCLOSURE

A signal processing system provides and processes a digital signal, converted from to an analog signal, which includes a noise component and possibly also an information component comprising small samples representing four mutually orthogonal items of measurement information representable as a sample point in a symbolic Cartesian four-dimensional spatial reference system. An information processing sub-system receives said digital signal and processes it to extract the information component. A noise likelihood determination sub-system receives the digital signal and generates a random noise assessment of whether or not the digital signal comprises solely random noise, and if not, generates an assessment of degree-of-randomness. The information processing system is illustrated as combat control equipment for undersea warfare, which utilizes a sonar signal produced by a towed linear transducer array, and whose mode operation employs four mutually orthogonal items of measurement information.
100. RECORD DIGITAL SIGNAL VALUES FOR ANALYSIS

101. IDENTIFY NUMBER OF SAMPLE POPULATIONS TO BE ANALYZED

102. SELECT A SYMBOLIC VOLUMETRIC REGION FOR PROCESSING

103. PARTITION REGION INTO SUBSPACE REGIONS

104. ENUMERATE QUANTITIES OF SUBSPACE REGIONS THAT ARE NON-EMPTY IN A RANDOM DISTRIBUTION

105. GENERATE STANDARD ERROR VALUE

106. GENERATE NORMAL DEVIATION STATISTIC

N FROM FIG. 2B TO FIG. 2B

FIG. 2A
107. DETERMINE WHETHER SAMPLE POINTS FOR ALL REGIONS HAVE BEEN PROCESSED

108. PERFORM STATISTICAL SIGNIFICANCE TESTS TO DETERMINE LIKELIHOOD THAT SAMPLE POINTS ARE RANDOMLY DISTRIBUTED
