YIELD AND BLAST ANALYSES  
WITH A  
UNIFIED THEORY OF EXPLOSIONS

FRANCIS B. PORZEL  
NAVAL SURFACE WEAPONS CENTER

## YIELD AND BLAST ANALYSES WITH A UNIFIED THEORY OF EXPLOSIONS (UTE)

### Summary

Yield is the most significant single number measured on any explosion because all effects --sympathetic reactions, fragments, blast damage-- derive from it. UTE offers the only adequate way to relate all explosions: non-ideal, any media, over all ranges in air, underwater, underground, confined spaces, heavy cases etc. The Form Factor and Lead Time are new extensions intended for safety analyses. A key idea in the form factor is to define average energy density in the blast wave relative to the peak value at the shock; it is the tacit assumption in scaling now. Lead Time means the difference in TOA between a sound signal and a shock wave; it scales, is a sensitive measure of yield and is nearly constant at long range. Applications include: absolute measure of prompt and delayed yields for blast, sympathetic reactions, fragments, propellant yield, surface effects, analysis with sparse data and simplified instrumentation.

# YIELD AND BLAST ANALYSES WITH A UNIFIED THEORY OF EXPLOSIONS

Francis B. Porzel

Naval Surface Weapons Center

## 1. UTE Methods for New NESIP Problems

Yield means the blast or hydrodynamic energy released by any explosive and is the single most significant number to be measured in tests of any explosion.

All effects derive from yield and in principle can be predicted using it:

- \* Primary fragments: their sizes, shape, number, initial velocity of trajectory,
- \* Close-in blast, regarding both initial containment and secondary fragments,
- \* Low pressure damage, especially to specify the range where 1 psi occurs,
- \* All sympathetic reactions -detonation, deflagration, burning, their degree- be it directly from blast or via fragment and thermal loads it produces.

In fact, the Maximun Credible Event (MCE) really means the overall yield.

The Unified Theory of Explosions (UTE)<sup>1</sup> was developed for just such needs. UTE offers the only general way to describe any explosion: nuclear, non-ideal HE, over all ranges in air, underwater, underground, confined spaces, heavy cases etc. UTE offers two dozen concepts as tools to treat dozens of real non-ideal effects, nearly all being unknown or ignored in idealized classic theory and hydrocodes. A key idea in UTE is "prompt vs delayed" energy; it asserts that natural processes release some energy instantly, some more slowly, reinforcing blast farther out; much is trapped behind the negative phase too late ever to support the shock front. This separation is manifest by phenomena like afterburning, secondary shocks, and the most dramatic feature of any explosion: The fireball is delayed energy.

The NESIP Technology Base<sup>2</sup> itself rests on the Unified Theory of Explosions and much success in NESIP tests is due to versatile and accurate analyses with UTE.

Current NESIP problems now raise new and more specific questions about yield. For sympathetic reactions and in the design of inhibitors to prevent them:

- \* How much energy is released in a partial or in a low-order detonation?
- \* What are the actual prompt and delayed fractions in afterburning explosives?
- \* How to live with the large scatter of pressures measured in the real world?
- \* How to live with the narrow range of feasible, affordable measurements?
- \* What are the absolute energies involved in various modes of energy release?

For hazards involving propellants:

- \* What are the yields of a propellant on an absolute basis, detonated alone?
- \* If set off by an explosive warhead, how much does the propellant add to the prompt or delayed yield of the main explosion? Any new hazards?

To meet these new needs for NESIP, two major advances have been developed for UTE:

- \* A "form factor" method for bookkeeping the energy within a blast wave, to describe variable rates of afterburning, notably in heavily aluminized HE.
- \* A "lead-time" method, a simple reliable way to get yield from time-of-arrival.

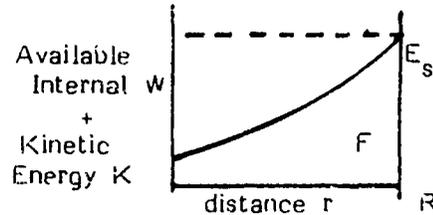

They have widespread application to many explosion problems for NESIP and others. The purpose of this paper is to describe these new methods briefly, show the code and to test them by comparisons with a broad spectrum of field measurements.

---

## 2. Form Factor Concept and Method

The form factor  $F$  is defined to mean the average hydrodynamic energy  $W+K$  in the wave relative to their peak sum  $E_s$  at the shock front. It is the ratio of the area shown here as  $F$  to the "square wave" as if  $E$  were constant at  $E_s$ .

If we define the yield  $Y(R)$  at any shock radius  $R$  as the integrated sum

$$Y(R) = 4\pi \int_0^R (W + K) r^2 dr$$

normalize the integral, multiplying/dividing by the peak overpressure  $P_s - P_0$ , and by the mean value of any factor (like the available fraction  $A$  of energy at  $P$ )

$$Y(R) = \frac{4\pi}{3} R^3 (P_s - P_0) A \int_0^1 \left[ \frac{W + K}{P_s - P_0} \right] \frac{3}{A} \left[ \frac{r}{R} \right]^2 \frac{dr}{R}$$

Thus  $F$  becomes the dimensionless fraction specified by the definite integral.

Rigorously, we can just simply define a form factor  $F$  such that

$$Y(R) = \left( \frac{4\pi}{3} \right) R^3 \frac{P_s - P_0}{P} A F$$

This definition for  $F$  is deceptively simple but is a powerful hydrodynamic tool. Many man-years and \$millions were spent since World War II on elaborate hydrocodes, mostly to calculate pressure-distance curves with highly over-simplified models. Yet, both  $A$  and  $F$  are readily prescribed by the overpressure ratio  $(P/P_0 - 1)$ ; so we can always obtain the shock radius  $R$  at any pressure  $P$  simply from

$$R^3 = \frac{Y(R)}{\left( \frac{4\pi}{3} \right) P A F} \quad P = \text{overpressure, units consistent with } Y \text{ and } R$$

To calculate  $R$ , the code decreases  $Y(R)$  from its initial value  $Y_0$  by decrements

$$dY = -4\pi \frac{Q}{\text{losses}} R^2 dR + \text{Afterburning gains}$$

This can be done in bold steps, decreasing the pressure about 25% at each step. The same steps are used also for integrating the time of arrival of the shock wave.

$A$  and  $F$  always appear together and here is an exact way to calculate  $AF$ . For exposition, let  $Q$  here mean the net loss (waste heat) and gain (afterburning). Then the ratio of the dissipation equation ( $dY=$ ) to the definition for  $F$  ( $Y=$ ):

$$\frac{dY}{Y} = \frac{-4\pi Q R^2 dR}{\left( \frac{4\pi}{3} \right) R^3 P A F} = -\frac{3(Q/P) dR}{AF R}$$

gives

$$\frac{dY/Y}{dR/R} = \frac{3Q/P}{AF} \quad \text{and} \quad AF = \frac{3Q/P}{d \ln Y / d \ln R}$$

The machine code uses the local value of  $d \ln Y / d \ln R$  from each previous step, because  $d \ln Y / d \ln R$  varies slowly, from about  $-0.5$  at high pressure to  $-1$  at low. Thus  $AF$  is bounded between  $6Q/P$  at high pressures and  $3Q/P$  at low pressure. Figure 1 shows these bounds and the transition region for the function  $AF$  vs  $P$ .

Analysis shows that  $AF$  goes like  $A(\text{shock})/3$  at high pressure, like  $AP^2/3$  at low, and a suitable approximation, to a few percent in  $Y$ , without use of  $d \ln Y / d \ln R$ , and with a single parameter  $1/3$  for both high pressures and low, is:

$$AF \cong \frac{A(\text{shock})}{3(1 + P_0/P)^2}$$

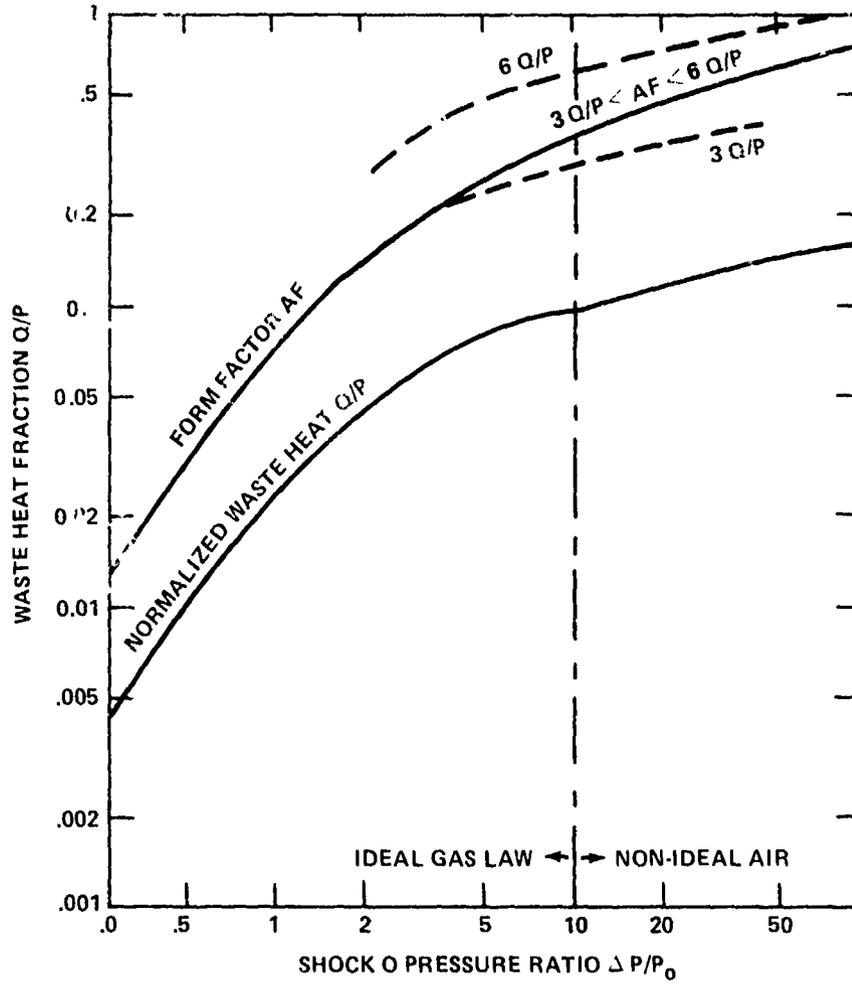

FIGURE 1. WASTE HEAT FRACTION AND FORM FACTOR VS. OVERPRESSURE

### 3. Lead-Time Concept and Method

Lead-time is a time-of-arrival method for measuring yield. With it we seek:

- \* An over-all measure of the shock history, sensitive to its early behavior.
- \* A way to circumvent uncertainty in yield from scatter in pressure measurements.
- \* Simpler instrumentation than the sophistication needed for good pressure data.

Time-of-arrival is an excellent measure for high pressure supersonic blast<sup>3, 4, 5</sup>; but at low pressure, TOA becomes sonic and an insensitive measure of shock strength. On the other hand, time-of-arrival can be measured with exceedingly high accuracy. Let us then measure the difference in time between the shock and a sound signal and define, at any range R:

$$\text{Lead-time} = \text{sound arrival} - \text{shock arrival time}$$
$$LT = \frac{R}{C_0} - T$$

This quantity ought to and does scale, is a sensitive measure at low pressures. Best of all, it becomes insensitive to the range at acoustic strength, so that one does not need an accurate gauge location --if the sound arrival is also measured.

As shown in Figure 2a, the early shock is highly supersonic:  $U \gg C_0$ . There

$$R = \int U dt \quad \text{or} \quad T = \int dR/U \quad \text{are both sensitive measures of yield.}$$

If we plot  $\ln R$  vs.  $\ln T$  as in Figure 2b, sound speed is a straight line, slope 1. But the shock time-of-arrival approaches it, partly because of the logarithmic plot. Also, the lead-time ceases to grow as the "overvelocity" vanishes at low pressure. As shown in Figure 2c, the lead-time approaches a scalable constant at long range.

In machine calculations, time-of-arrival adds up, using the same steps as for  $Y(R)$ :

$$TOA = \int dR/U \quad U = \text{local shock velocity}$$

Because of the finite step size, an average value for  $1/U$  is used; thus

$$dT = T_{i+1} - T_i = [1/U_{i+1} + 1/U_i] * [R_{i+1} - R_i] / 2$$

The time-of-arrival and the lead-time are scaled just as for distance scaling.

When the shock is strong, it is convenient, and a more independent measure to scale

$$\text{Relative yield} = (\text{Measured TOA/reference TOA})^3.$$

When the shock is weak (below the transition pressure) we scale lead-times as

$$\text{Relative yield} = (\text{measured LT/reference LT})^3.$$

Figures 3 and 4 illustrate practical reasons for developing the lead-time method.

Large scatter in field pressure measurements is no doubt real, probably intrinsic, because a pressure gauge "feels" only the pressure at its surface, regardless of how rapidly pressure may vary in a boundary layer next to that surface<sup>6, 7</sup>.

Figure 3 shows how pressure suffers from real variations both in space and in time. Spacewise, the dust-laden boundary layer, brush, rough terrain all deplete yield.

Timewise, the shock jets, and "rings" as it goes, in patterns that shift with time.

The time-of-arrival will more nearly follow the grand-scale average growth of the hemisphere in free air above the ground surface, as idealized in Figure 4.

While some lag may occur due to drag in the boundary layer, the corresponding error in lead-time is not nearly as severe as the pressure reduction from the same layer.

Field measurements will test whether this expectation of less scatter is realized.

We also expect the lead-time will better "remember" the early history of the wave.

If the explosion starts at low speed, is then sustained by afterburning, the TOA could be longer, the lead-time less, than by an instantaneous explosion.

On the other hand, compensation occurs: the energetic shock wastes more energy early and after running a long time more slowly, may arrive later than the afterburner.

UTE form factor calculations will show which is the stronger effect and how much.

#### 4. Machine Code and Printout

Appendix A lists the complete code, is well-annotated and may be self-explanatory. Written in advanced BASIC for a personal computer, it uses two-digit variables, compound statements in lines etc., but in principle could be copied and run as is.

Input parameters appear at the top of the printout (Tables 1, 2). They include:

Trial yield  $Y_0$ , here in joules;  $4.188 \cdot 10^{12}$  joules = 1 KT,  $4.188 \cdot 10^6$  = 1 KG,  
Mass  $M$  of explosive and immediate case, their specific energy  $H$  relative to air,  
Initial radius  $R_0$ : HE charge, isothermal sphere (nuclear), isobaric sphere (gas),  
Ambient conditions: pressure  $P_0$ , sound speed  $C_0$ , and/or density  $D_0$ ,  
Afterburning fraction  $AB$  of  $Y_0$ ; Transition pressure  $P_t$ , strong to weak shock.  
If any above are missing, the code usually supplies a default value or computes one.  
Input measurements for evaluation of yield include pressure  $P$ , range  $X$ , and/or TOA.

Major Options are included regarding input parameters, input data, and print-out.

Input any 3 of 4: yield  $Y_0$ , initial pressure  $P_1$ , mass  $M$  or specific energy  $H$ .

If any are omitted (usually  $P_1$  is unknown), the code will calculate it.

If all are given, the code will recompute  $H$  to make it consistent with the rest.

If  $P$ ,  $X$  or  $T$  data are omitted; the code prints predictions anyway.

Time may be input either as discrete data or by a fitted curve. (So could distance).

Print-outs can be predictions only, + diagnostics, or yield analyses with graphs.

Major Computation Blocks (15 in all) are set off by remarks in the LIST.

Of interest as a guide to the code, they are listed on the first page of Appendix A.

Computation Procedure. After the predictions for conditions at the charge radius:

1. Select a new pressure; next data or reducing the previous  $P$  by  $10^{-1} = 1/1.26$ .
2. Compute waste heat  $Q$ , afterburning increment  $YA$ , available energy fraction  $A$ , form factor  $w/A$  as  $AF$ , shock velocity  $U$ ; all are functions of the pressure.
3. Compute yield decrement  $Y_1$ , afterburning  $YA$ , new yield  $Y = Y_i - Y_1 + YA$ , then iterate for "mass-corrected" radius  $Z = (R^3 + H \cdot M)^{1/3}$ , then get  $R$  from  $Z$ .
4. Calculate TOA from  $dT = dR/U$ , and new TOA = old TOA +  $dT$ .
5. Calculate relative yield from range, essentially as (measured/calculated)<sup>cubed</sup>.
6. Calculate relative yield from TOA or lead-time, as (measured/calculated)<sup>cubed</sup>.
7. Summarize with an average yield relative to input yield, for range and/or TOA including the standard deviation of the measured yields about their mean.

Table 1 illustrates a printout of close-in predictions of a massless explosion:  $M=0$ .

The initial pressure  $P_1$  and radius  $R_0$  mark the end of a nuclear radiative phase.

The isothermal sphere implies a "square wave", i.e. larger form factor than normal,

nor can the interior gas be accelerated instantly to reproduce a normal blast wave.

The code allows it to do so gradually by computing an "inertial mass" as shown.

The point is: In a gaseous explosion, spark gap, or any other non-ideal blast wave,

a like initial dissimilarity occurs and will be so accommodated with all UTE codes.

We note that the inertial mass found, 544 kg  $\cong$  mass of air engulfed at that radius.

Table 2 illustrates another printout option that graphs the relative yield from TOA.

It compares predicted lead-times for a Mk 48 torpedo with the field test data.

Initial yield included a ground reflection factor 1.5 and afterburning of PBXN 103.

The ambient conditions are for the test site at Socorro, NM, altitude  $\cong$  5200 feet.

The input mass was 1038 pounds, essentially the warhead, most of which is PBXN-103.

This was the very first test of the code. The relative yield is plotted as  $T$  (time).

The TOA yield, .90 predicted, means lead-time itself is within  $.9^{1/3} = .965$ , 3.5%.

Also shown, not plotted, are the pressure results: relative yield 1.099, 3.2% in  $R$ .

## 5. Test of Methods with Nuclear and HE Data

The form factor and lead-time methods were tested against a broad spectrum of data. Nuclear data check on absolute yields by their radiochemical and hydrodynamic yields and check the equation of state more severely at higher pressures than HE reaches. HE data check non-ideal effects like large mass, afterburning, and secondary shocks. The broad range of data checks for self-consistency and exposes systematic errors. Figures 6 to 10 graph the detailed results and Table 3 summarizes them.

Blast theory is usually checked against data by pressure-distance plots like Fig. 5. But as seen there, UTE matches composite data so closely that graphs are inadequate. Instead, UTE computes the relative yield at each pressure level and we plot that. On Figure 5, the line widths approach 3% in radius, 10% in yield, too small to see. On Figures 6 to 10, the three central lines are relative yields of  $1.0 \pm 10\%$ , as if the graph of Fig 5 were blown up to broaden the lines to the band width shown.

1 KT Nuclear Composite<sup>1, 7</sup> (Fig 6) covers from 13600 to .07 bars,  $10^5$  times. <sup>7</sup>  
The average yield 1.024 KT  $\pm 5.3\%$  matches the line width of the source curve <sup>7</sup>  
and is significant because the high pressures are superbly accurate fireball data.  
The TOA yields also are excellent at high pressures; overall is 1.08 KT  $\pm 14\%$ .  
The excursion at low pressures is probably due to a fitted time-of-arrival curve.  
The consistency in yield is assurance that the high pressure UTE equation of state  
is realistic relative to the ideal gas law, used for air at pressures below 10 bars.

KING Fireball<sup>3</sup> (Fig 7) is probably the best pressure-distance data in existence:  
high yield, air drop, negligible mass effect, all-fission, a perfect circle fireball.  
Radiochemistry gave 545 KT, hydrodynamic yield 555 KT, fireball scaling 595 KT.  
Here, pressure and TOA both give 586 KT; scatter of 3-7% is round-off error in data.  
This one test is definitive: all the measured data are digital --no graphing errors.

Nuclear Blast Standard<sup>8</sup> (Fig 8) is not data but an artificial viscosity hydrocode.  
The absolute value of yield .997 KT checks superbly, but the scatter is over 14%.  
Its initial pressures are known to be 50% low, from actual fireball theory <sup>and data</sup>.  
At low pressure its P-R curve decays like  $R^{-1.1}$ , flatter than UTE,  $P \sim R^{-1.5}$ .  
Classic theory predicts  $R^{-1}$ , but field measurements always decay much faster.

1 KG TNT Composite<sup>9</sup> (Fig 9): splendid agreement/consistency, up to the charge <sup>1.4</sup>  
and for  $.07 < P/P_0 < 2$ , the UTE calculation agrees well with often-measured  $P \sim R^{-1}$ .  
The excursion below .07 bars is probably not real, but old data piously fit to  $R^{-1}$ .  
The absolute yield is .714 KG, 714 cal/gm; earlier UTE methods gave 720 cal/gm.

1KG H6 Composite<sup>9</sup> (Fig 10) is a check with a heavily aluminized explosive,  
where the afterburning fraction is estimated as .30. The consistency 5% is superb.  
The absolute yield is 1.014 KG HE, or 1014 cal/g, equivalent to 1.4 times TNT.

Previous UTE, DSC<sup>1</sup> (not shown) has been used successfully on so many NESIP and  
other tests that it is of interest to use a DSC calculation ( $M=0$ ) as input data here.  
The result: Relative yield 1.00000,  $\pm 3.5\%$ , no sensible difference between them.

## 6. MK. 48 Torpedo Inhibitor Tests

Recent field experiments on the design of inhibitors<sup>2, 10</sup> for the Mk 48 torpedo provide an opportunity to test/apply these new methods to a typical NESIP problem. The test set-up is shown at the top of Table 4; essentially, it was a donor warhead flanked by two acceptor warheads, with inhibitor plates between them, on each side. On one side the plates were steel, on the other side aluminum, thicknesses as shown. Detonation was suitably instrumented with witness plates, cameras and flash panels and in a blast line by pairs of pressure-time gages near 140, 240, 300, 400 feet. Even so, critical questions arise in all such tests:

If the witness plate did hole, did full detonation of the entire warhead occur?

If it did not hole, could the charge have moved and a delayed detonation occur?

To understand either case, we need to measure the yield output for each event.

The test results were unequivocal and corroborative among all the test evidence. Shots 1 and 2: no acceptor detonated. Shot 3: the aluminum side holed in situ. The 140 and 240 foot gages on Shot #3 had double pulses that coalesced by 300 feet. Still the critical questions remain: How much energy did each shot yield?

Peak pressure results are compared on Figure 11 with the pre-shot calculations. The data on #1 seem somewhat low, on #2 somewhat high. But scatter makes it doubtful: Excepting two "low" points on #1, one "high" on #2, 13 remaining points replicate. Shot #3 leaves no doubt the curve beyond 300 feet represents twice the yield.

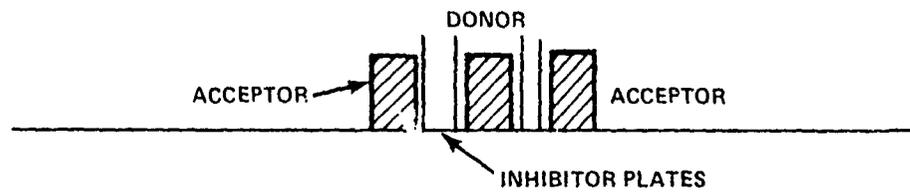

The corresponding pre-shot estimates and lead-time data are shown on figure 12. Now there is no doubt that Shot #2 was larger than #1, nor that Shot #3 was double. Considering this was the first test of a lead-time prediction on HE, it checks well.

Relative yields on shots 1 and 2 are plotted on Figures 13-14, summarized on Table 4. Compare the pressure results: 1012 KG  $\pm$  21.1% vs. 1386 KG  $\pm$  17.9%. The ratio 1386/1012 = 1.37 is impressive, except that 37% is not far different from the arithmetic or the Pythagorean sum of deviations, 21.1+17.9. One is just not sure. Now compare lead-time yields: 828 KG  $\pm$  7.8% vs. 1108 KG  $\pm$  6.8%. Again: 1108/828 = 1.34 is impressive and 34 is more than twice any sum of 7.6 and 6.8. These confidence levels make a strong, objective case for the merits of lead-time.

As Table 4 indicates, the yields on shot 3 were definitely doubled, by either method. but no predictions had been made with history effects for catch-up of second pulses.

We have yet to resolve why the lead-time gives lower yields on both shots 1 and 2. Compare range/lead-time: 1012/828 = 1.23 (shot 1) and 1306/1108 = 1.25 (shot 2). It is precarious to prognosticate with preliminary data until they really do firm up, but two main ideas are noteworthy here: 1. measuring sound velocity, 2. reflection. Among many ways to measure sound velocity -- absolute temperature + wind velocity, a microcharge fired just before the main shock, or compute  $C_0$  from the P-t data-- all three differed at the field tests, and we have not yet resolved why. On the other hand, the lead-time could well be telling us a real fact: The calculations assumed the torpedo explosion reflected instantly off the ground. Whereas we know it must have run for some time as a free air explosion, and was slowed by the inhibitor plates and by the acceptor in that direction. We also know that the shock is slowed by the dust-load in the boundary layer. The present results are based on sound velocity as calculated from pressure gages.

TABLE 4.

## 7. Conclusions

1. Form Factor. The form factor method with the unified theory of explosions (UTE) agrees well with nuclear and high explosive data, with earlier methods of UTE and offers a facile way to describe non-ideal and non-spherical explosions.

2. Lead-Time. The lead-time method is a simply instrumented way to measure yield at high and low shock strengths, with much less scatter than pressure measurements.

3. UTEFORM. Form factor and lead-time together offer a new powerful diagnostic tool to solve the unpredictably broad problems which explosion safety requires such as sympathetic reactions, early blast history, unusual afterburning or energy release.

4. Absolute Yield. The definition  $10^{12} \text{ cal/KT} = 10^6 \text{ cal/KG} = 10^3 \text{ cal/gm}$  is a modern rational way to correlate any explosion: nuclear, chemical, other source. It is necessary because:  
Different HE's do not necessarily scale with each other nor with other sources. That is, equivalent weight is certainly not constant at high shock strengths and is not necessarily constant even at acoustic shock strengths.

## Appendix A

### LIST for UTEFORM Form Factor and Lead-Time Methods With the Unified Theory of Explosions

#### Major Computation Blocks by Line Numbers:

0-199 Input parameters  
200-299 Compute  $P_1$  given  $Y_0$  and  $H$   
299-300 Compute  $M$  or  $H$ , given  $Y_0$ ,  $P_1$  and either  $M$  or  $H$   
400-450 Compute trial  $Y$ , if unspecified  
450-500 Print column headings  
500-570 Data processing and pressure selection  
570-699 Energy gains, losses, new yield and range  
700-800 Equation of state sub-routine  
800-850 Energy gain and loss sub-routines  
850-899 Form factor sub-routines  
900-999 Time-of-Arrival sub-routine  
1000-1400 Input data: pressure, distance, time  
1400-1500 Example: Fitted time-of-arrival sub-routine for a nuclear composite.  
1500-1599 Relative yields from range and time-of-arrival  
1600-2000 Yield, standard deviations and termination.

#### Hints:

1. Any consistent set of units may be used.  
If energy is in joules,  $R$  in meters,  $M$  in kg, then  $P$  is in pascals  $=10^{-5}$  bars.  
Line 50, as written, converts from  $KT$  ( $4 \pi/3 * 10^{12}$ ) to joules;  
use line 51 to enter the  $KT$ ,  $KG$  or  $cal/gm$ .
2. Change data with a line editor, it will save retyping the remarks in that line.
3. In general, the variables are defined by remarks the first time used in the LIST.
4. For help. call Fran Porzel, 202 394 1166 (office) or 703 533 7973 (home).
