ABSTRACT

The polarographic reduction of pentaerythritol mononitrate in unbuffered aqueous solution at pH 1-4, gave two well defined waves which are shown to be diffusion controlled. However from examination of the wave equation the electrode processes in each case are found to be irreversible. The first wave, not pH dependent, has a mean half wave potential, $E_1^d = -0.439$ volt and is assigned to the electrode reduction of the nitrate function, through a two-electron change. The second wave which appears at a more negative potential, approximately $-1.0$ volt, is pH dependent and is shown to arise from the reduction of nitrous acid through a four electron change. This wave disappears at pH's above 4.

In buffered solutions under acidic conditions the first wave has a mean half wave potential, $E_1^d = -0.416$ volt. Under basic conditions, however, $E_1^d$ shifts to more negative values. This shift in $E_1^d$ is interpreted as arising from complex formation of pentaerythritol mononitrate and the borate anion of the buffering system.
CONCLUSION

Both waves observed from the polarographic reduction of pentaerythritol mononitrate (PEMN) at low pH values, i.e. pH 1 - 4 are amenable to quantitative determination as demonstrated by the rate of change of the diffusion current with concentration. Hence polarography should be considered as an efficient technique for the quantitative determination of pentaerythritol mononitrate on microsize samples. The ability of pentaerythritol mononitrate to participate in complex formation with the borate anion which results in significant shift in the half wave potential, $E_1/2$, should provide a valuable tool in the identification of this nitrate ester when admixed with other nitrates.

Since our major concern however is to gather sufficient experimental data so that a thorough understanding of the reduction process is acquired, it is evident that considerably more work is needed to meet this objective. Before we can assess for example the magnitude of structural and substituent effects on the free energy of reduction we must first critically examine extraneous influences on the process of reduction such as solvent and ionic strength.

RECOMMENDATIONS

The data already obtained in aqueous solutions should be complemented with additional experiments on the binary solvent, water-ethanol. The solubility spectrum of the pentaerythritol nitrates varies greatly with the number of nitrate groups. While pentaerythritol mononitrate (PEMN) is quite soluble in water, pentaerythritol tetranitrate (PETN) on the other hand is
practically insoluble but does have a broad range of solubility in organic solvents including ethyl alcohol. Consequently in order to study these nitrates on a comparative basis we must not only find a solvent mixture common to all nitrate esters of pentaerythritol but also determine the effect of solvent composition on the reduction process.
INTRODUCTION

Our interest in organic nitrate esters led us to explore the merits of Polarography as an analytical tool in the study of these compounds. Of even greater importance to us was the belief that possibly some correlation between the half wave potential, $E_{1/2}$, of nitrate esters and such well known effects as inductive, mesomeric or steric could be observed. Indeed linear free energy relationships have been reported for other families of compounds (Ref. 1-4). Any structural correlation that could be found between $E_{1/2}$ and neighboring substituents should give some greater insight into the mechanism of reduction.

We also rationalized that since $E_{1/2}$ for the reduction and oxidation processes must be related to the bond energies of the function, the polarographic behavior of various nitrate compounds should to a first approximation correlate with other properties of interest such as thermal stability and vibrational energy.

The first polarographic study of nitrate esters was reported in 1952 by Kaufman and co-workers who studied the reduction at the dropping mercury electrode of ethyl and cyclohexyl nitrates (Ref. 5). A two electron reduction mechanism with alcohol and nitrite ion as products was established and found to be consistent with the experimental data. This mechanism seems to have been tacitly accepted by all workers who have since reported results on other organic nitrate esters. The list of nitrate esters so far studied comprises the following: pentaerythritol tri- and tetranitrate, glycerol trinitrate, ethylene glycol dinitrate, mannitol hexanitrate, n-butyl nitrate, ethyl nitrate
and cyclohexyl nitrate (Ref. 5-11). The bulk of this work however has been essentially analytical in nature with little concern regarding the fundamental mechanism of reduction or the effect of structure on the half wave potential, $E_1$. 

For a number of reasons presented below the nitrate esters of pentaerythritol appeared attractive for the initial phase of our study. Every molecule, from pentaerythritol to pentaerythritol tetranitrate (PETN), has a tetrahedral configuration around a central carbon atom with little steric crowding of the functional groups (Ref. 12, 13). Molecular models also show that although the overall symmetry of the molecule decreases in going from the tetra- to the mono-nitrate, even the latter approaches the shape of a spherical body and consequently the Stokes-Einstein equation can be applied with sufficient confidence in the determination of diffusion coefficients. Consequently this series provides us with four different molecules having a different number of nitrate functions which however are subjected to the same electronic and steric environment. Lastly, of the four nitrate esters in this series, the di-, tri-, and tetranitrate were available in sufficient purity for the polarographic study. Thus, our efforts in the preparation of these compounds would be limited to the synthesis of pentaerythritol mononitrate. In the present communication we will concern ourselves solely with the synthesis and polarographic reduction of pentaerythritol mononitrate (PEMN).
RESULTS AND DISCUSSION

A. Preparation of Pentaerythritol Mononitrate (PEMN).

Three different methods were investigated for the preparation of PEMN. The first two, controlled nitration of pentaerythritol and hydrolytic denitration of pentaerythritol trinitrate (PETriN), although very attractive because of their simplicity, did not yield the desired product. There is however not enough ground to believe at this time from the limited number of experiments conducted that these routes should be considered impractical.

The third approach which proved to be successful, the reductive denitration of pentaerythritol tetranitrate (PETN), was suggested to us from a publication which appeared in 1962 (Ref. 14). All three approaches are briefly described below.

Controlled Nitration of Pentaerythritol (PEOH)

The preparation of PETriN through a controlled nitration of Pentaerythritol with mixed acids (HNO$_3$ + H$_2$SO$_4$ + H$_2$O) is a well established manufacturing process and leads to relatively high yields and purity of the desired trinitrate. It seemed that this procedure with minor modifications could be extended to the preparation of the mononitrate which could subsequently be separated from the mixture of nitrates by column chromatography on silica gel. This method of preparation was consequently tried in a few experiments but all attempts failed to yield enough PEMN for characterization. The use of 98% nitric acid diluted in methylene chloride was also briefly explored with no better results. In every case, these approaches favored the formation of the
higher nitrates even under conditions which resulted in high percentage of unreacted pentaerythritol.

**Denitration of Pentaerythritol Trinitrate (PETriN)**

A calculated quantity of aqueous sodium hydroxide was added to an ethanolic solution of PETriN and the mixture was left standing at room temperature. At various intervals of time, aliquots of this solution were withdrawn and analyzed for residual base. When it was judged that the hydrolysis had proceeded far enough the mixture was worked up and separated into its various components. Besides unreacted PETriN and small amounts of the dinitrate (PETN), only solid polymeric material melting above 300°C was recovered. This procedure was modified by using an alcoholic solution of potassium hydroxide as the hydrolytic agent. After working up the product mixture the results seemed to parallel those obtained above. Only the higher nitrates and some condensation polymers could be detected.

**Reductive Denitration of Pentaerythritol Tetranitrate (PETN)**

Simecek (Ref. 14) in 1962 described the reaction of pentaerythritol tetranitrate (PETN) with hydrazine hydrate which yields all four nitrates in various proportions depending on the stoichiometry of the reactants. A graph showing the variation in products distribution with the ratio of N₂H₄·H₂O to PETN used was also given. Based upon this graph the maximum yield of mononitrate was predicted at a N₂H₄·H₂O/PETN ratio of 3/1 moles per mole. Using this procedure at this ratio of the reactants we have not been able to produce PETN. Under these conditions we have obtained only PETriN, the dinitrate
PEDN as the major product, and also a yellow oil which on the basis of nitrogen analysis is believed to be a mixture of higher molecular weight nitrate esters arising possibly through condensation reactions.

This procedure was repeated with the following modifications: a) The ratio of N2H4·H2O/PETN was raised to 3.5/1 moles per mole, b) Also the residue from the acidified solution (see experimental p. 24) was given a more thorough extraction consisting in refluxing with several ether portions which were subsequently combined, dried, and evaporated. These modifications resulted in a significant decrease in the proportion of PETrIN in the products. However PEDN was still the major product and in addition only a non-crystallizable yellow oil having a nitrogen content of 4.81% could be recovered (Calculated for PEDN 7.73%).

A third attempt followed with these further changes in the procedure: a) The ratio N2H4·H2O/PETN was raised to 4.5/1, b) In order to minimize the formation of condensation polymers under strongly acidic conditions, the acidification step (see experimental, p.24) was controlled by means of a pH meter to a minimum pH 3.9 and the evaporation of the acidified solution was stopped as soon as a noticeable increase in viscosity was observed. With this modified procedure PETrIN was absent in the products mixture and the quantity of polymeric material was sensibly decreased. Pentaerythritol mononitrate as an oil, which crystallized upon standing, was obtained from both ether extracts in a 25% yield. Recrystallization from chloroform yielded pure crystals, m.p. 78.0 - 78.5°C, percent nitrogen: found 7.66% calculated 7.73%.
B. Polarographic Study of Pentaerythritol Mononitrate (PEMN).

Initial experiments were conducted on a solution of the supporting electrolyte alone at different pH's for the purpose of establishing:

a) The magnitude of the residual current and its rate of increase with increasing applied potential, b) The half wave potential of the hydrogen ion and its variation with concentration, c) The appearance potential of the supporting electrolyte discharge.

The residual current increases very slowly and regularly with an increase in potential up to the discharge of the electrolyte which begins at -1.9 volts. At this potential the residual current reaches a maximum value of 0.30 microamperes which is less than 10% of the current produced by the reducible specie. Consequently errors arising in the correction of the residual current should be negligible. A wave is observed prior to the discharge of the electrolyte whose diffusion current ($i_d$) and half wave potential ($E_{1/2}$) are function of the solution pH as shown in Fig. 1 & 2. At pH's above 4 this wave disappears. The fact that the $i_d$ increases in a near linear relationship with the hydrogen ion concentration leaves little doubt that this wave arises from the reduction of hydrogen ions.

Aqueous solutions of the supporting electrolyte varying in pH from 1 to 12 and containing $5 \times 10^{-4}$M of pentaerythritol were also polarographed in order to determine if this substance when present as an impurity during the determinations of the nitrates would interfere with the electrode process. Furthermore since the first three nitrates of pentaerythritol, PEMN, PEDN, and
PETriN possess besides the nitrate function from one to three hydroxyl groups in their molecular structure, a knowledge of the behavior of pentaerythritol at the dropping mercury electrode would indirectly establish if the hydroxyl function itself interferes in the reduction process. It was found that pentaerythritol under these conditions is completely inert at the dropping mercury electrode as shown in the polarograms which paralleled those obtained with the supporting electrolyte alone.
Reduction of Pentaerythritol Mononitrate (PEMN) in Unbuffered Aqueous Solutions.

In this medium the reduction of PEMN gives rise to two waves in acid solution (pH 1-3) while at higher pH's only the first wave remains. The experimental data are summarized in Table I. This wave, which as shown below, varies linearly with the concentration of PEMN is believed to be due to the reduction of the nitrate function. The average position of the half wave potential \( E_{1/2} \) for the range of pH's studied is at -0.430 volt with a standard deviation of 0.016 volt. Although this wave does not appear to be pH dependent a rather broad range in the value of \( E_{1/2} \) is observed, i.e., 0.044 volt. We should certainly anticipate better constancy in half wave potential values. The presence of small quantities (five drops of a 0.1% solution) of the maximum suppressor methyl red which was added to every polarographic solution might be responsible for this erratic behavior. The quantity, \( E_{3/4} - E_{1/4} \) included in Table I gives a measure of the steepness of the rise of the polarographic wave. Suffice to say in connection with the quantity \( E_{3/4} - E_{1/4} \) that its magnitude appears to vary with the position of \( E_{1/2} \).

When \( E_{1/2} \) shifts to more negative values, \( E_{3/4} - E_{1/4} \) increases in magnitude.

1 The potential values reported in Table I are those of the applied potential which were not corrected for the cell resistance. We have measured the cell resistance under these conditions and found it to be 1700 \( \Omega \). This resistance would lower the \( E_{1/2} \) values only by a maximum of three millivolts for the first wave and five millivolts for the second wave.
It was noted that the height of the first wave is a linear function of the PEMN concentration as shown in Fig. 3 & 4 where the limiting current was plotted vs. the concentration in PEMN for both acidic (pH 2) and basic (pH 9) media respectively. It is deduced therefore that the electrode process is diffusion controlled. The number of electrons transferred at the electrode was calculated from the Ilkovic equation below.

\[
n = \left[ \frac{i_d}{C m^{2/3} t^{1/6}} \right] \left[ \frac{1}{607 \text{ pl}^{1/2}} \right] \tag{1}
\]

\( n \) = Number of electrons consumed by the electroactive species.

\( D \) = Diffusion coefficient of the electroactive species (cm\(^2\) sec\(^{-1}\)).

\( C \) = Concentration of the electroactive species (moles/liter.).

\( m \) = Average rate of flow of mercury through the capillary (mg/sec.).

\( t \) = Drop time (sec.).

\( i_d \) = Average diffusion current (microamperes).

In this equation only the diffusion coefficient \( D \) needs to be measured in a separate experiment, or alternatively the value of \( D \) can be calculated by means of the Stokes-Einstein relation (2).

\[
D = \frac{2.96 \times 10^{-7}}{\eta (V_m)^{1/3}} \text{ cm}^2\text{ sec}^{-1} \text{ at } 25^\circ \text{C} \tag{2}
\]

\( \eta \) = Viscosity of the medium at 25°C.

\( V_m \) = Apparent molar volume of the reducible species in the pure solid state. (mol.wt./density).

This relationship will give an accurate value of \( D \) provided that the reducible
specie is essentially a spherical molecule and that it is sufficiently larger than the solvent molecules so that all retarding forces may be treated as frictional. It is believed that for PEMN both these criteria are met. Using as an approximate value of viscosity for the aqueous medium that of water at $25^\circ$C, i.e., $8.94 \times 10^{-3}$ dyne cm. and from the measured density of PEMN ($d=1.48$g./cc.) a value for the diffusion coefficient of PEMN of $6.67 \times 10^{-6}$ cm.$^2$ sec.$^{-1}$ was obtained.

The number of electrons transferred for the electrode process which gives rise to the first reduction wave as calculated from equation (1) is very close to two for all pH's studied (Table 1). Consequently the result of the present study are in agreement with the previous findings of Kaufman (Ref.5). Having established that the electrode process occurs with the transfer of two electrons it is then possible from the Ilkovic equation (1) to obtain an experimental value of the diffusion coefficient $D$ which could be compared with the value $6.67 \times 10^{-6}$ cm.$^2$ sec.$^{-1}$ calculated from the Stokes-Einstein equation (2). Referring to Fig. 3 & 4 where the limiting current was plotted vs. the concentration in PEMN the experimental diffusion coefficient of PEMN is found to be $7.45 \times 10^{-6}$ cm.$^2$ sec.$^{-1}$ at pH 2.0 and $6.91 \times 10^{-6}$ cm.$^2$ sec.$^{-1}$ at pH 9.0. The deviation from the calculated value (equation 2) is 11.7% at pH 2.0 and 3.5% at pH 9.0. In our views this is a reasonable agreement between experimental and calculated values.

In order to obtain further insight into the reaction mechanism we have examined the polarographic data obtained in light of the wave equation(4).
\[ E_{d,e} = E^*_f - \frac{0.0591}{an} \log \frac{i}{i_d} \cdot i \] (4)

\( E_{d,e} \) = Reduction potential at the dropping mercury electrode corresponding to the reduction current, \( i \).

\( a \) = Transfer coefficient for the electrode reaction.

\( n \) = Number of electrons involved in the rate determining electron-transfer step.

\( i_d \) = Diffusion current or maximum current of the polarographic wave.

From a plot of \( \log \frac{i}{i_d} \cdot i \) versus the corresponding potential \( E_{d,e} \), it is found that the points do not fall on a straight line but a strong curvature of the experimental line is usually observed in the neighborhood of \( E^*_f \). Two typical plots are shown in Fig 5 & 6 for reductions carried out at pH's 1.0 and 10.1. In fact two straight lines can be drawn which meet at about \( E^*_f \). From the slope of these lines the value of the product, \( an \), was calculated and these values for the whole range of pH's investigated are given in Table II. The value of the product, \( an \), being much lower than two, the number of electrons transferred at the electrode, demonstrates the irreversibility of the overall electrode process.

It is tempting to give a mechanistic significance to the fact that a change in slope is observed in the neighborhood of the half wave potential, \( E^*_f \). One wonders if this behavior does not reveal two consecutive one-electron steps at the electrode instead of a single two-electron step. As shown in equation (5) the primary electrode process would be the transfer (reversible) or irreversible) of one electron to the nitrate function followed by abstraction
of a proton either from the hydronium ion or a water molecule. The second step at the electrode would involve another transfer of one electron to the intermediate (I) with the subsequent rearrangement of species (II) to yield the products, alcohol and nitrous acid.

\[
R - O - N_0^+ + e \rightarrow R - O - N_0^{OH}
\]  
\[
R - O - N_0^{OH} + e \rightarrow R - O - N_0^{OH} \rightarrow R - O + HO-NO
\]

If both electron transfer steps are irreversible this situation then reduces to a case of two consecutive electrochemical reactions. On the other hand if the first step consists of a reversible electron transfer the overall electrode reaction would involve a potential determining step. Both cases have been treated by Delahay in his theory of irreversible polarographic waves (Ref. 21).

A very convenient way to obtain values of \( an \) is shown in equation (7).

(Ref. 23) This relation is derived from the equation of a totally irreversible wave involving only a single rate determining electron-transfer step at 25°C (Ref. 22). Applying equation (7) to the case under study gave values of \( an \) shown in Table III. These new \( an \) values calculated from equation (7) are much closer to those of \( an_2 \) than \( an_1 \) (Table II). Possibly then, the second
step in the proposed mechanism for the reduction of PEMN (equation o) is rate determining. In addition since the magnitude of the transfer coefficient is generally close to 0.5 we may infer from our results that only one electron is involved in the rate determining electron-transfer step.

The second wave observed in the reduction of pentaerythritol mononitrate is located in the neighborhood of -1.0 volt. The analysis of this wave which is observed only in acidic media is rendered difficult by the close proximity of the intense hydrogen wave. The second wave appears more or less as a shoulder on the steep rising portion of the hydrogen wave. Consequently in the absence of a well defined plateau, accurate estimation of the diffusion current, \( i_d \), for the second wave rests of course a great deal on the judgement of the experimentalist. The interpretation offered in the following discussion is arrived at with full awareness of this limitation in the precision of the experimental data.

The second wave has the following features: a) Only at pH's below 4 is this intense and well defined wave observed; b) The half wave potential, \( E_1 \), is pH dependent, shifting to more negative values with an increase in pH (Fig. 7); c) The value of \( E_{3/4} - E_{1/4} \) increases with increasing pH's (Fig. 8); d) Plots of \( E_{d.e.} \) versus \( \log i_i/i_d \) yield curves consisting of two segments which meet in the neighborhood of \( E_2 \) (Fig. 9); e) The values for the product, \( \alpha \), obtained from these curves are much less than one and decrease with increasing pH (Table IV).
All this information points to the fact that this wave is related to a process which must involve the hydrogen ion in the rate determining step. Using relation (7) for an irreversible process new values of the product, \( m_n \), for this wave are obtained (Table V) which check quite closely with the \( a_{n_2} \) values obtained from the wave equation (Table IV). The limiting current on the other hand does not appear to follow any regular pattern with the change in pH. It seems consequently that this limiting current at high negative potentials is not controlled by some electrode kinetic process but is a true diffusion current which would depend entirely on the rate of mass transfer to the electrode. This was confirmed by measuring the change of the limiting current with the concentration of PEMN. As shown in Fig. 10, a plot of the limiting current versus the concentration of PEMN gives a straight line which passes through the origin. Since this current is diffusion controlled we can by means of the Ilkovic equation (8) determine the number of electrons

\[
\nu = \frac{i_d}{607 \ C \ \frac{d^2 \ m^2}{3 \ t} \ 1/6}
\]

transferred at the electrode surface. The value of the diffusion coefficient \( D \) for the reducible species or intermediate which gives rise to this wave must by necessity be the same as the diffusion coefficient of its precursor, i.e., PEMN which was found to be \( 7.45 \times 10^{-6} \ \text{cm}^2 \text{.sec}^{-1} \) at the same pH. Inserting this value into equation (8) and solving for \( \nu \) gives 3.9 for the number of electrons participating in the electrode process. If this wave arises from the reduction at the electrode surface of nitrous acid (equation 6) the consumption of four electrons during this process could then indicate that
the electrode process is the reduction of nitrous acid to hydroxylamine as shown in equation (9). (Ref. 18, 19, 20)

\[
\text{HO-NO} + 4e^- + 4H^+ \rightarrow \text{HO-NH}_2 + H_2O \quad (9)
\]

Returning to Table I, it is seen that a third wave is present at pH 3.1. From its position, \( E_2 = -1.470 \), there is not much doubt that this wave arises from the reduction of \( H^+ \) in the medium. It's value interestingly enough corresponds to a hydrogen ion concentration (Fig. 1) of \( 1 \times 10^{-4} \) or to a pH4. This confirms the general view that in unbuffered solutions the hydrogen ion concentration at the electrode surface decreases relative to the bulk concentration during the reduction process.
Reduction of Pentaerythritol Mononitrate (PEMN) in Buffered Aqueous Solutions

As shown above when working with unbuffered solutions there is always the danger that the hydrogen ion concentration in the immediate vicinity of the electrode surface becomes depleted making virtually impossible a study of the effect of pH on the reduction process. In buffered systems on the other hand, any change in concentration of $\text{H}^+$ would be immediately compensated through the buffering mechanism and consequently constancy in pH at the electrode surface results. Three buffers were chosen to cover the pH range of 1 to 12. The results of PEMN reduction under these conditions are given in Table VI. Up to and including pH 5.90 the first wave appears at an average of -0.418 volt with a standard deviation of 0.015 volt. This wave then appears at more positive potential than that observed in the unbuffered system discussed previously. Since the ionic strength in both series of experiments was kept the same, this difference in the average value of $E$ ($\Delta = 0.013$ volt) must be traced to nature of the different supporting electrolytes used in these two series and more specifically to the different cations used, $(\text{CH}_3)_4\text{N}^+$ for unbuffered and $\text{K}^+$ for buffered solutions. The diffusion constant, $i_d/Cm^{2/3}t^{1/6}$ is also slightly lower on the average in the buffered medium by approximately 3% relative to the unbuffered medium.

In one respect the behavior of the reduction in buffered solutions is in direct contrast to what had been observed in unbuffered solutions. Whereas in the latter, the function $F_{3/4} - E_{1/4}$ was found to increase with more
negative half wave potentials, in buffered solutions, $E_{3/4} - E_{1/4}$ decreases with increasing half wave potentials as shown in Fig. 11. No satisfactory explanation can be offered at this time for this behavior. The characteristics of the second wave observed at pH's below 4 parallel the previous findings in unbuffered solutions (Fig. 12) except for the diffusion constant which is found to increase with the pH of the solution (Table VI). In unbuffered solutions (Table I) the diffusion constant did not vary in a regular fashion with the pH of the solution. However as mentioned previously the absence of a well defined plateau in the profile of the second wave throws some doubt in the validity of the diffusion current measurements. From pH's between 8 and 12 use was made of boric acid-borate electrolyte and this change in the buffering system has a significant effect on the half wave potential, the diffusion constant and the function $E_{3/4} - E_{1/4}$. The magnitude of these effects is shown in Table VI and Fig. 13 and 14. This behavior is indicative of the formation of a charge complex with PEMN. This should not be too surprising since it is well known that polyhydroxy alcohols and borate ions interact in solution to form complexes (Ref. 15) The formation of these complexes is not limited to vicinal diols but include also 1,3-diols, consequently PEMN whose structure is shown below would be anticipated to complex with the borate ion.

$$\begin{align*}
\text{O}_2\text{NCH}_2\text{CH}_2\text{OH} & \quad \text{CH}_2\text{OH} \\
\text{HOCH}_2 & \quad \text{CH}_2\text{OH} \\
1,3
\end{align*}$$

20
By analogy with Hermans' proposed structure for polyhydroxyborate complexes (Ref. 16, 17) we can postulate for PEMN-Borate complex the following structure.

\[
\begin{align*}
&O_2NCH_2-C-CH_2OH \\
&CH_3-C-CH_2 \\
&O - B - O \\
&HO - OH
\end{align*}
\]

The presence of a negative charge in the structure should certainly raise the energy barrier for the reduction process occurring at a negative electrode and thus a shift in \( E_1 \) to more negative potential would be predicted. Also since complex formation leads to an increase in molecular weight this should be reflected in a decrease in the diffusion coefficient, hence a lowering in the diffusion current, \( i_d \). Superimposed will be the dragging effect from the presence of a negative charge in the structure. Both \( i_d \) and \( E_1 \) experimental values are in qualitative agreement with these views.

There is no doubt that both free PEMN and its complex co-exist in the solution at the pH's we have studied. This is very nicely indicated by the spreading in the values of \( E_{3/4} - E_{1/4} \), which suggests that we are indeed dealing with a composite wave rather than a single wave. The function \( E_{3/4} - E_{1/4} \) could thus be a valuable tool for estimating the extent of complex formation.

Analysis of the waves (equations 4) obtained in buffered system yielded plots similar to those obtained in the unbuffered system. The \( an_1 \) and \( an_2 \) values are given in Table VII and Table VIII. It will be observed that the
transfer coefficient $a$ decreases significantly in the presence of the borate buffer at high pH. This is substantiated by calculating $an$ values using equation (7) as shown in Table IX.
EXPERIMENTAL

1. Preparation of Pentaerythritol Mononitrate (PEMN)

Reductive Denitration of Pentaerythritol Tetranitrate (PETN)

Into a 500 mls. r.b. flask equipped with a condenser and addition funnel was placed 63.2g. (0.20 mole) of PETN dissolved in a mixture of 120 mls. of ethanol and 120 mls. of dioxane. An aqueous solution of hydrazine hydrate, $\text{H}_2\text{N}_2\text{H}_4\cdot\text{H}_2\text{O}(85\%)$ containing 35.3g. (0.60 mole) of base was transferred into the addition funnel and added dropwise over a period of one hour to the reaction flask which had been previously heated to 74°C. After the addition was completed the mixture was heated and kept under reflux (79°C - 80°C) for two and one half hours. The solvent was removed at 35-40°C under a reduced pressure of 15mm. and the residue was taken up in water. Pentaerythritol trinitrate (PETriN) separated as a reddish oil (Product I).

The aqueous layer was extracted several times with diethyl ether and the combined ether extracts were dried over sodium sulfate and after removal of the solvent yielded a yellow oil identified as pentaerythritol dinitrate (PEDN). Percent nitrogen: found 12.11% Calculated for PEDN, 12.39%. (Product II).

The water layer was next acidified with 2N $\text{H}_2\text{SO}_4$ until the gas evolution ceased. The acidified solution was then extracted several times with diethyl ether, and the ether extracts were combined and dried over sodium sulfate. Removal of the solvent yielded a yellow oil. Percent nitrogen: found 3.6%. (Product III). The same procedure was repeated with the following modifications: a) the ratio $\text{N}_2\text{H}_4\cdot\text{H}_2\text{O}/\text{PETN}$ was raised from 3/1 to 3.5/1 moles per mole, b) the
residue from the acidified solution was subjected to a more thorough extraction procedure which consisted in refluxing with several ether portions.

Product I - Reddish oil, which was characterized as PETriN was formed in lesser amounts than in the original procedure.

Product II - Yellow oil, identified as PEDN was still the major product.

Product III - Yellow oil which could not be crystallized. Nitrogen analysis: found 4.8%N.

The procedure was further modified as follows: a) the ratio \( \text{N}_2\text{H}_4 \cdot \text{H}_2\text{O} / \text{PETN} \) was raised to 4.5/1 moles per mole, b) the acidification step was monitored with a pH meter and not allowed to proceed beyond a pH 3.9, c) the evaporation of the acidified solution was stopped as soon as a noticeable increase in viscosity was observed.

Product I - No product separated at this step indicating the absence of both PETN and PETriN in the mixture.

Product II - Yellow oil, 25.31g. (0.112 mole) identified as PEDN possibly admixed with some PEMN, was still the major product. Nitrogen analysis: found 11.50%. Yield: 56.0%.

Product III - Yellow oil, 8.51g (0.047 mole) which crystallized upon standing. Recrystallization from chloroform gave colorless crystals, m.p. 78.0 - 78.5°C. Nitrogen analysis: found 7.66%, Calculated for PEMN, 7.73%. Yield 23.5%.

A summary of the stoichiometric conditions for these experiments is given below:

2. **Polarographic Study of Pentaerythritol Mononitrate (PEMN)**

The polarograms were run on a Sargent Model XXI Polarograph used in the No. 1 damping position. A commercial H type polarographic cell was used for all reductions, with the cross-arm filled approximately to $1/3$ with a 3% solution of agar saturated with KCl, acting as a salt bridge. Mercury, calomel and solid KCl were placed in the reference compartment which was filled with a saturated KCl solution, the whole forming a large-surface saturated calomel electrode against which all potentials were measured. Throughout the study the polarographic cell was kept in a thermostated water bath maintained at $25^\circ \pm 0.1^\circ$C. The concentration of PEMN for most experiments was chosen as 0.5 millimoles per liter and the solutions prepared by adding a calculated amount of a stock solution, $10^{-2}$ M in PEMN to a measured volume of the polarographic solution containing the electrolytes and five drops of alcoholic methyl red (0.1%) as the maximum suppressor. The pH's, measured on a Beckman Model 76 pH meter, were adjusted with small volumes of HCl, NaOH or $(\text{CH}_3)_4\text{NOH}$ as needed. The ionic strength of the solutions was kept constant at 0.1M. The dropping electrode capillary characteristics, $m$ and $t$, were set to give a value of $m^{2/3}t^{1/6}$ equal to 2.037 mg $2/3\text{sec}^{-1/2}$.

The polarographic reduction of pentaerythritol mononitrate in unbuffered aqueous solution at pH 1-4, gave two well defined waves which are shown to be diffusion controlled. However from examination of the wave equation the electrode processes in each case are found to be irreversible. The first wave, not pH dependent, has a mean half wave potential, $E_1 = -0.439$ volt and is assigned to the electrode reduction of the nitrate function, through a two-electron charge. The second wave which appears at a more negative potential, approximately -1.0 volt, is pH dependent and is shown to arise from the reduction of nitrous acid through a four-electron charge. This wave disappears at pH's above 4.

In buffered solutions under acidic conditions the first wave has a mean half wave potential, $E_1 = -0.416$ volt. Under basic conditions, however, $E_1$ shifts to more negative values. This shift in $E_1$ is interpreted as arising from complex formation of pentaerythritol mononitrate and the borate anion of the buffering system.

INSTRUCTIONS

1. ORIGINATING ACTIVITY: Enter the name and address of the contractor, subcontractor, grantee, Department of Defense activity or other organization (corporate author) issuing the report.

2. a. REPORT SECURITY CLASSIFICATION: Enter the overall security classification of the report. Indicate whether "Restricted Date" is included. Marking is to be in accordance with appropriate security regulations.

2b. GROUP: Automatic downgrading is specified in DoD Directive 5200.10 and Armed Forces Industrial Manual. Enter the group number. Also, when applicable, show that optional this report directly from the group number. (C).

3. REPORT TITLE: Enter the complete report title in all capital letters. Titles in all cases should be unclassified. If a meaningful title cannot be selected without classification, show title classification in all capitals in parenthesis immediately following the title.

4. DESCRIPTIVE NOTES: If appropriate, enter the type of report, e.g., interim, progress, summary, annual, or final. Give the inclusive dates when a specific reporting period is covered.

5. AUTHOR(S): Enter the name(s) of author(s) as shown on or in the report. Enter last name, first name, middle initial. If military, show rank and branch of service. The name of the principal author is an absolute minimum requirement.

6. REPORT DATE: Enter the date of the report as day, month, year, or month, year. If more than one date appears on the report, use date of publication.

7a. TOTAL NUMBER OF PAGES: The total page count should follow normal pagination procedures, i.e., enter the number of pages containing information.

7b. NUMBER OF REFERENCES: Enter the total number of references cited in the report.

8a. CONTRACT OR GRANT NUMBER: If appropriate, enter the applicable number of the contract or grant under which the report was written.

8b. b. & c. PROJECT NUMBER: Enter the appropriate military department identification, such as project number, subproject number, system numbers, task number, etc.

9a. ORIGINATOR'S REPORT NUMBER(S): Enter the official report number by which the document will be identified and controlled by the originating activity. This number must be unique to this report.

9b. OTHER REPORT NUMBER(S): If the report has been assigned any other report numbers (either by the originator or by the sponsor), also enter this number(s).

10. AVAILABILITY/LIMITATION NOTICES: Enter any limitations on further dissemination of the report. Other than those imposed by security classification, using standard statements such as:

1. "Restricted Data" is included. Marking is to be in accord-
2. with all security classification of the report. Indicate whether
3. "Qualified requesters may obtain copies of this
4. report from DDC."
5. "All distribution of this report is controlled. Qualified
6. DDC users shall request through...

If the report has been furnished to the Office of Technical Services, Department of Commerce, for sale to the public, indicate this fact and enter the price, if known.

11. SUPPLEMENTARY NOTES: Use for additional explanatory notes.

12. SPONSORING MILITARY ACTIVITY: Enter the name of the departmental project office or laboratory sponsoring (purchasing) the research and development. Include address.

13. ABSTRACT: Enter an abstract giving a brief and factual summary of the document indicative of the report, even though it may also appear elsewhere in the body of the technical report. If additional space is required, a continuation sheet shall be attached.

It is highly desirable that the abstract of classified reports be unclassified. Each paragraph of the abstract shall end with an indication of the military security classification of the information in the paragraph, represented as (TS), (S), (C), or (U).

There is no limitation on the length of the abstract. However, the suggested length is from 150 to 225 words.

14. KEY WORDS: Key words are technically meaningful terms or short phrases that characterize a report and may be used as index entries for cataloging the report. Key words must be selected so that no security classification is required. Identifiers, such as equipment model designation, trade name, military project code name, geographic location, may be used as key words but will be followed by an indication of technical context. The assignment of links, rules, and weights is optional.
