MEMORANDUM
RM-4474-PR
FEBRUARY 1965

DYNAMIC PROGRAMMING, GENERALIZED STATES, AND SWITCHING SYSTEMS

Richard Bellman

This research is sponsored by the United States Air Force under Project RAND, Contract No. AF 49(638)-700 monitored by the Directorate of Development Plans, Deputy Chief of Staff, Research and Development, Hq USAF. Views or conclusions contained in this Memorandum should not be interpreted as representing the official opinion or policy of the United States Air Force.

DLC AVAILABILITY NOTICE
Qualified requesters may obtain copies of this report from the Defense Documentation Center (DDC).

Approved for OTS release

The RAND Corporation
PREFACE

Part of the Project RAND research program consists of basic supporting studies in mathematics. In this Memorandum the author presents an alternative mathematical approach to a type of general problem arising in the study of control processes.
SUMMARY

Control problems associated with the linear vector system

\[ \frac{dx}{dt} = Ax + f(t), \quad x(0) = c, \]

with \( f(t) \), the control vector, subject to nonclassical constraints, have received a great deal of attention in recent years. In particular, let us cite the "bang-bang" process where each component of \( f(t) \) is allowed to assume only two distinct values.

In this paper, we present an alternative formulation in dynamic programming terms which is independent of the dimension of \( x \), the state vector. It is based upon an extension of the concept of state variable and has application to a number of systems with switching characteristics. In its simplest form, the approach was used in the study of adaptive control processes.

DYNAMIC PROGRAMMING, GENERALIZED STATES, AND SWITCHING SYSTEMS

1. INTRODUCTION

Control problems associated with the linear vector system

\[
\frac{dx}{dt} = Ax + f(t), \quad x(0) = c,
\]

with \( f(t) \), the control vector, subject to nonclassical constraints, have received a great deal of attention in recent years. In particular, let us cite the "bang-bang" process where each component of \( f(t) \) is allowed to assume only two distinct values; see [1,2,3]. Other references will be found in these sources.

Although there are many approaches with varying degrees of effectiveness now available, it cannot be said that the problem of numerical solution of problems of this genre has been completely resolved. The situation is, of course, even more unsatisfactory when the basic equation describing the system is nonlinear. In this paper we wish to make a contribution to the general problem by considering the case where \( f(t) \) has only one nonzero component. We may consider that this type of problem arises in the case where the system is described by a scalar equation of the form
(1.2) \[ u^{(N)} = g(u^{(N-1)}, \ldots, u, t, v(t)), \]

where \( v(t) = \pm 1 \). It should also be pointed out that this particular control process can be used as the basis of a method of successive approximations. We shall return to this point below.

Control processes of general type, with or without constraints, can readily be formulated in dynamic programming terms; see [4], [5]. Numerical application of this formulation is limited at the present time by the limited rapid-access storage capacities of current digital computers.

In what follows, we present an alternative formulation in dynamic programming terms which is independent of the dimension of \( x \), the state vector. It is based upon an extension of the concept of state variable and has application to a number of systems with switching characteristics. In its simplest form, the approach was used in the study of adaptive control processes; see [5], [6].

2. EXTENDED STATE

In the classical formulation of descriptive and control processes, the state of the system is defined to be the minimal set of data required to determine the future behavior of the system; see [5], [7]. Let us now
expand this concept in the following manner. The extended state of a system is an algorithm which permits us to calculate the state.

The point of this is that specification of the algorithm may require very little rapid-access storage. On the other hand, time is required for the calculation. Thus, as usual, we are trading time for rapid-access storage. This idea has been used both in our previous work in dynamic programming and in quasilinearization [8].

3. DISCRETE SWITCHING PROCESS

Consider the vector difference system

\[
\begin{align*}
    x_{n+1} &= g(x_n, y_n), \quad x_0 = c, \\
\end{align*}
\]

where \( y_n \) is a control vector subject at each time to the condition that it belong to a constraint set \( R, y_n \in R \). Since we are thinking in terms of a digital computer calculation, there is no loss of generality in beginning with a discrete process. Let it be required to choose the \( y_n \) in \( R \) so as to minimize

\[
    \| x_N - z \|,
\]

where \( \| \cdot \| \) denotes some measure of the deviation of \( x_N \) from \( z \).
Writing

(3.3) \[ f_N(c) = \min_{y_n \in \mathbb{R}} \|x_N - z\|, \]

we readily obtain the recurrence relation

(3.4) \[ f_N(c) = \min_{y \in \mathbb{R}} f_{N-1}(g(c,y)), \quad N \geq 1, \]

\[ f_0(c) = \|c - z\|. \]

If the dimension of \( x_n \) is large, this is not computationally feasible; see [9] for discussion.

4. ALTERNATIVE FORMULATION

Let us now consider the case where each \( y_n \) has only one nonzero component, say the first, which can assume only the values \( \pm 1 \). Then a policy consists of a choice of \( +1 \) for \( T_1 \) stages, \( -1 \) for \( T_2 \) stages, and so on, or \( -1 \) for \( T_1 \) stages, \( +1 \) for \( T_2 \) stages, and so forth.

We therefore introduce the extended states

(4.1) \[ [+T_1,T_2,\ldots,T_k], \quad [-T_1,T_2,\ldots,T_k] \]

at time \( n = T_1 + T_2 + \cdots + T_k > 0 \). The first state indicates that \( +1 \) has been used for \( T_1 \) stages, \( -1 \) for the next \( T_2 \) stages, and so on. We suppose that all
\[ T_1 \] are positive. With the aid of the equation in (3.1), we can now calculate the actual state in phase space.

Introduce the two functions

\[
\text{(4.2)} \quad f^+_N(T_1, T_2, \ldots, T_k) = \text{distance from } z \text{ at the end of } N \text{ stages, starting in extended state } [+, T_1, T_2, \ldots, T_k],
\]
and using an optimal policy,

and \( f_N(T_1, T_2, \ldots, T_k) \), defined similarly.

The principle of optimality now yields, in the usual fashion, the functional equations

\[
\text{(4.3)} \quad f^+_N(T_1, T_2, \ldots, T_k) = \min[f^+_{N-1}(T_1, T_2, \ldots, T_{k+1}), f^+_{N-1}(T_1, T_2, \ldots, T_k, 1)],
\]

for \( N \geq 1 \), with \( f^+_0(T_1, T_2, \ldots, T_k) = g(T_1, T_2, \ldots, T_k) \), a quantity calculable using (3.1), and

\[
\text{(4.4)} \quad f^-_N(T_1, T_2, \ldots, T_k) = \min[f^-_{N-1}(T_1, T_2, \ldots, T_{k+1}), f^-_{N-1}(T_1, T_2, \ldots, T_k, 1)],
\]

for \( N \geq 1 \), with \( f^-_0(T_1, T_2, \ldots, T_k) \) calculable.
The quantity \( \min_{y_n} \| x_N - z \| \) is given by \( \min[f_{N-1}^+(1), f_{N-1}^-(1)] \).

5. COMPUTATIONAL ASPECTS

If the dimension of \( x_n \) is large, and we restrict the number of switchings and the duration of the process suitably, it is easy to see that the formulation of Sec. 4 requires considerably less rapid-access storage than the usual formulation of Sec. 3.

Let us also point out that in the case where \( y_n \) has a number of nonzero components, we can use the foregoing procedure as a method of successive approximations; see the discussion of the general Hitchcock–Koopmans–Kantorovich scheduling problem in [9].

6. PRODUCTION PROCESSES

In a number of production and experimentation processes, the equation describing the system takes the form

\[
\begin{align*}
(6.1) \quad x_{n+1} &= A_n x_n + y_n, \quad x_0 = c,
\end{align*}
\]

where the matrices \( A_n \) are to be chosen subject to constraints. These may be treated in the same way as above.
