BIOLOGICAL SCIENCES LABORATORIES

Project 1B562602A059
September 1969
In conducting the research described in this report, the investigators adhered to the "Guide for Laboratory Animal Facilities and Care," as promulgated by the Committee on the Guide for Laboratory Animal Facilities and Care of the Institute of Laboratory Animal Resources, National Academy of Sciences-National Research Council.

ACKNOWLEDGMENT

We acknowledge the excellent technical assistance of Mr. Orville Brand, who performed the complement-fixation tests.

ABSTRACT

The plaque assay system developed in this laboratory for the typhus, spotted fever, and scrub typhus groups of rickettsiae is also appropriate for Coxiella burnetii.
A PLAQUE ASSAY FOR COXIELLA BURNETII*

In several recent reports,1-3 we demonstrated that a convenient and sensitive plaque assay system had been developed for the typhus, spotted fever, and scrub typhus groups of rickettsiae. We now report that this same plaque assay procedure has been successfully employed with Coxiella burnetii.

The organism used in this study, the AD strain of C. burnetii, was originally isolated from raw milk in California in 1948.4 Our working seed consisted of 107 yolk sac suspensions, prepared in brain heart infusion broth (BHIB), of the 10th yolk sac passage of this strain.

The plaque assay procedure used in this study was the same procedure described in more detail in earlier reports.2,3 Twenty-four-hour chick embryo primary monolayers in 30-ml plastic tissue culture bottles were infected for 15 minutes with serial tenfold dilutions (in BHIB) of C. burnetii. The infected monolayers were then covered with 5 ml of an overlay of medium 199 (5% calf serum) containing agarose at a final concentration of 0.5%. The monolayers were incubated in a closed system at 32 C for 8 to 11 days. Plaques were stained by adding an overlay containing neutral red as described earlier.2

The plaque morphology of the AD strain of C. burnetii is shown in Figure 1. This strain produces small (approximately 1 mm), somewhat indistinct plaques, which are morphologically similar to plaques formed by typhus and scrub typhus rickettsiae.1,3 Although plaques produced by C. burnetii are small, plaque counts are easily determined.

Studies were initiated to compare the plaque titer with the 50% infectious dose (ID₅₀) in mice.5 Groups of eight 16- to 18-g male Swiss mice (Fort Detrick strain) were injected IP with 0.1 ml of serial tenfold dilutions of C. burnetii suspensions in BHIB ranging from 10⁻⁶ through 10⁻¹⁵. Twenty-two days later the animals were bled and the complement-fixation titers of the sera were determined using commercially prepared (Lederle) Nine Mile strain of C. burnetii as antigen. Sera having a complement-fixation titer of 1:8 or greater were considered positive. The ID₅₀ was then computed by the Spearman-Kärber method of calculation. The plaque titers of three ampoules from the same seed pool were determined in parallel with the ID₅₀ determination.

A comparison of the mouse ID₅₀ with the plaque titer demonstrated that the ID₅₀ assay is more sensitive for C. burnetii than the plaque titration procedure. The seed pool had a mouse ID₅₀ titer of 9.75 log₁₀/ml and an average plaque titer of 8.4 log₁₀/ml. There was less than one-tenth log difference among the plaque titers of the three ampoules tested.

FIGURE 1. Plaques Formed by Coxiella burnetii on Chick Embryo Primary Monolayers. From left to right, $10^{-6}$, and $10^{-7}$ dilutions of inoculum.
Although the plaque assay procedure for C. burnetii is somewhat less sensitive than the ID$_{50}$ assay, it offers some advantages. The plaque assay is faster (10 days compared with 22), far less laborious, much more economical, and provides the opportunity to isolate organisms from a single focus of infection. For many experimental purposes these advantages may offset the reduced sensitivity of the system.

The results of these and previous tests\textsuperscript{1-3} indicate that the plaque assay system developed in this laboratory is a sensitive titration procedure for diverse types of rickettsiae. We have been successful in obtaining plaques with representative species of each of the four groups of these organisms. Moreover, we have not found any rickettsiae that we have not been able to plaque. These findings demonstrate that this assay may be appropriate for all rickettsiae, and should facilitate studies of these organisms.

We are unable to explain why this procedure has been successful where others have failed. In a few preliminary studies we varied several procedures in the assay, but no single factor could be identified as the key to the success or failure of the procedure. Further studies are necessary to elucidate the critical steps in this plaque assay procedure.
