Compliance
Stress Intensity Factor

Abstract:
The K calibration at the deepest point of a circular surface flaw in an internally pressurized thick-walled cylinder has been determined by a compliance test as well as a three-dimensional collocation method. Compliance is defined as the change in the internal volume of a cylinder divided by an applied hydrostatic pressure instead of the usual elongation/load definition. It is shown, using the linear theory of elasticity that the derivative with respect to the crack depth of internal and external volume changes are equal.

(See Other Side)
This permits the use of external strain measurements to compute the stress intensity factors. Periodic cubic splines are used to interpolate/approximate the strain data as well as to compute external volume change as a function of crack depth. The results agree very well with theoretical results obtained by the three-dimensional collocation method.

INTRODUCTION

The compliance calibration for two-dimensional cracks is seldom attempted. This is due to the fact that a fairly wide selection of methods (e.g., finite elements, collocation, complex variable, integral equations, etc.) are available to obtain stress intensity factors to a good degree of accuracy and also due to difficulty in performing experiments with sufficient accuracy. For the three-dimensional problems, in general, the difficulties are compounded, analytically as well as experimentally. However, for an internally pressurized thick-wall cylinder with a symmetric internal surface flaw located in the axial direction, the evaluation of compliance can be accomplished. This has been done by proper definition of compliance and data reduction. In fact, a fatigue crack originating at the bore surface tends to be orientated with its length in the axial direction and depth in the radial direction.

The theoretical basis for the compliance test using the linear theory of elasticity is given in Section one.

With a starter notch of a semi-circular cross-section an extensive set of tests were performed as explained in Section two. In the third section, the method of numerical data analysis is outlined, and the stress intensity factors are computed. In Section four, we simulate the actual crack by a simpler geometry and using the method of three-dimensional collocation, the stress intensity factors are computed. The experimental results compare well with the theoretical results obtained. To the authors' knowledge, such a $K_1$ calibration does not exist in the literature.
FIGURE 1. Cross sections showing a surface flaw in the gun tube.
SECTION I - ANALYSIS OF COMPLIANCE CALIBRATION

The volumetric compliance method for a thin, straight-fronted radial notch has been discussed in [1]. For the present problem of a symmetric surface flaw located on an axial plane shown in Figure 1, it is clear that strain energy release rates and stress intensity factors are functions of the axial coordinate $x_3$. However, if we restrict our attention to the plane $x_3=0$ only, the concepts of volumetric compliance can be extended to compute the stress intensity factors at the deepest point of the surface flaw, i.e. at $x_3=0$. Let the following quantities be defined at $x_3=0$: $\Delta V_i$ is the change in the internal volume per unit length in $x_3$, due to the internal pressure $p$; $G$ is the crack extension force (strain energy release rate); $C_V = \Delta V_i/p$ is the volumetric compliance, and $b$ is the crack depth. Then,

$$G = \frac{1}{2} \rho^2 \frac{dc_V}{db} \quad \text{at } x_3=0 \quad (1)$$

The stress intensity factor at $x_3=0$, denoted by $K_1$, is

$$K_1 = \frac{E}{(1-\nu^2)} G = \frac{E p^2}{2(1-\nu^2)} \frac{d(\Delta V_i/p)}{db} \quad \text{at } x_3=0 \quad (2)$$

The above relation is a consequence of a 'plane strain' condition at $x_3=0$, [2]. As indicated in (2), the compliance calibration can be

accomplished at a given value of pressure by determining the change in the internal volume of the cylinder (at $x_3=0$) for a series of surface flaws of different depths and performing the indicated differentiation. However, the measurement which can easily be made is the change in the outside volume of the cylinder per unit length at $x_3=0$ (equivalent to the change in cross-sectional area at $x_3=0$). In the sequel we will prove that the derivative of internal and external volume changes for a given pressure is identical. $\Delta V_0$ and $\Delta V_m$ are the changes in the outside volume and material volume per unit length at $x_3=0$. Hence

$$\Delta V_0 = \Delta V_i + \Delta V_m$$  \hspace{1cm} (3)

If $\delta V$ is the total change in the material volume $V$ bounded by cylindrical surfaces $S_1$ and $S_2$ between cross-sections $S_5$: $x_3=\lambda$ and $S_6$: $x_3=-\lambda$ and exterior to the upper and lower surfaces of the surface flaw $S_3$ and $S_4$, Figure 1, we have

$$\delta V = \int_V e \, dV \hspace{1cm} (4)$$

where $e = e_{11} + e_{22} + e_{33}$ is the dilation. The generalized Hooke's law for a homogeneous isotropic body can be written (using the usual notations) in the following form: (see e.g. [3])

$$\tau_{ij} = \lambda \delta_{ij} e + 2\mu e_{ij} \hspace{1cm} (i,j = 1, 2, 3) \hspace{1cm} (5)$$

Contraction gives:

$$\tau_{ij} = (3\lambda + 2\mu)e \hspace{1cm} (6)$$

Hence

$$\delta V = \frac{1}{3\lambda+2\mu} \int_V \tau_{ii} \, dV \hspace{1cm} (7)$$

Using the equation of equilibrium

$$\tau_{ik,k} = 0 \quad (i, k = 1, 2, 3) ,$$

one can show:

$$\int_V \tau_{ij} \, dV = \int_V \left( \tau_{ik} x_j \right)_k \, dV .$$

The divergence theorem yields

$$\int_V \left( \tau_{ik} x_j \right)_k \, dV = \int_S \tau_{ik} x_j \, dS = \int_S \tau_{ik} x_j \, dS$$

where $S$ is a surface forming the complete boundary of the volume $V$ and $\tau_{ik}$ are the direction cosines of the outer normal $\nu$ of $S$ and $T_1$ are the components of the traction $T$ acting on $S$. Hence we have from (9) and (10)

$$\int_V \tau_{ij} \, dV = \int_S \nu \, \tau_{ij} \, dS$$

and contraction gives

$$\int_V \tau_{ii} \, dV = \int_S \nu \, \tau_{ii} \, dS = \int_S \nu \cdot \tau \, dS$$

The surface $S$ in Figure 1 is formed by six surfaces denoted by $S_1$, $S_2$, \ldots, $S_6$ then

$$\Delta W_m = \frac{\Delta V}{2} = \frac{1}{2\kappa} \frac{1}{3\lambda + 2\mu} \sum_{n=1}^6 \int_{S_n} (\nu) \cdot \tau \, dS$$

where $(\nu)_n$ are tractions on the surface $S_n$. From the symmetry we have $(\nu)_3 = (\nu)_4$ and $(\nu)_5 = (\nu)_6$ and the outer normals are in opposite directions for each pair $(S_3, S_4)$ and $(S_5, S_6)$. The last four integrals, having possibly the crack depth $b$ as a parameter, vanish. This completes the proof that $\Delta W_m$ is independent of $b$. 
FIGURE 2. Schematic diagram showing the specimen for compliance test.
For a pressurized cylinder we have $(T)_1 = -e_r p$, $(T)_2 = 0$, where $e_r$ is a unit vector in the radial direction. Thus
\[ T_r = \frac{1}{2} \frac{d}{dr} \left( 2pr_1^2 \right) \]  
and from (13)
\[ \frac{\Delta \gamma}{2} \frac{dr}{db} = \frac{d\gamma}{db} \]  
The stress intensity factor then can be written in terms of the outside volume change of the cylinder per unit length
\[ K_I = \frac{E}{\pi(1-\nu^2)} \left( \frac{dV_o}{db} \right)^{1/2} \] at $x_3 = 0$

**Section 2**

The specimen, made from a steel cannon tube, was a cylinder with a 7.1 inch smooth bore and a 14.25 inch outside diameter, giving a diameter ratio of 2.007 and a wall thickness of 3.575 inches. The length was 30 inches with a recess 1.5 inch long and 7.3 inch diameter at each end for the pressure seal.

It was tested as a vertical, hollow cylinder, internally pressurized on a supporting mandrel so that the end loads were supported by the internal mandrel, giving an open end condition. (See Figure 2.) The cylinder ends were sealed with threaded closures on the mandrel so that there were no axial stresses produced in the specimen due to pressure end loads. The pressure fluid was a synthetic instrument oil which remains fluid at pressures in excess of those used. The pressure was fully exerted in the initial notch cavity when the cylinder was pressurized.

Not Taken Due To Failure
The wall was initially notched with a semi-circle of 1/4 inch radius cut at the bore by electrical discharge machining (EDM). The notch was 1/2 inch long in the axial direction, 1/4 inch deep in the radial direction and 0.030 inch wide in the circumferential direction at the midsection of the specimen. A fatigue crack was grown from this starter notch by hydraulic pressure cycling from zero to 48,000 psi until it reached each successive desired depth, as determined by ultrasonic crack-depth measurement. The circumferential strains were then read on the outside circumference with bonded foil strain gages at 14 angular positions relative to the notch location.

The strain gages were 1/4 inch gage length and were oriented in the circumferential direction in a ring at specimen midlength. Two gages were located on a line directly over the notch, one at 1 inch above and one at 1 inch below the cylinder midlength, so as to permit measurement of crack depth at its deepest point by placement of an ultrasonic normal probe directly over the notch. Other gages were located around the midlength circumference at angles from 50° to 180° on either side of the notch line, as listed in Table 1.

When measuring the strains at each crack depth, the pressure was increased to 16000, 32000 and 48000 psi and then decreased to 40000, 32000, 24000, 16000, 8000, 4000 and zero. The pressures were controlled within ±1%. The readings from all gages were taken in sequence, with the cylinder held at pressure, using a 24 channel switching unit and an SR-4 strain indicator located outside the test cell. An identical strain gage, bonded to an unstrained piece of the same steel lying on the
test specimen provided temperature compensation during the experiments. If the final strain reading at zero pressure differed from the initial zero pressure reading by more than 20 microinches per inch at any crack depth the readings were repeated to eliminate measurement errors as much as possible.

Strain gage data for the 48000 psi pressure level are listed for the successive crack depths in Table 1. The gage positions are the angular locations on the O.D. from a point directly over the initial notch.

Figure 3 shows the final fracture surface of this fatigue crack.

The crack profile at successive crack depths is reproduced in Figure 4. The corresponding number of cycles to reach each depth is given in Table 1. Figures 3 and 4 show that the crack, propagated from the initial semi-circular notch, remained a semi-circle until nearly 2-inch depth was reached. After that it became part-circular or part-elliptical. It finally acquired the shape of a partially imbedded ellipse, when the intersection of the crack front with the bore surface became nearly stationary while the ellipse deepened and lengthened. In these latter stages of growth, after a 2-in. depth, the rate of propagation was quite fast. Unfortunately we did not obtain as complete strain data as would be required for an accurate compliance analysis for the greater depths. The data is therefore analyzed for the semi-circular shape up to the 2-inch depth only. In Figure 3 one can see the evidence of a “free surface shear-lip” formation which fans out at about 20° from the inner wall on either side of the initial notch.
FIGURE 3. The final fracture surface of a Fatigue Test Specimen.
FIGURE 4. Crack profiles at successive crack depths.
SECTION 3 - DATA ANALYSIS

By considering only the cross-section of the cylinder through the strain gages (i.e., $x_3=0$), the numerical problem is stated as follows.

Given the tangential strain at selected points on the circumference of a circle, we wish to determine numerically the change in cross-sectional area (equivalently $\Delta V_0$, the change in external volume per unit length at $x_3=0$).

This can be accomplished in two ways. First, we can integrate the tangential strain to obtain the change in the length of the perimeter

$$\Delta P = \int_0^{2\pi} r_2 \varepsilon_\phi(\phi) \, d\phi \quad \text{at} \quad x_3=0 \quad ,$$

and assuming the distorted figure remains circular, we have the change in cross-section area $\Delta A_0$:

$$\Delta A_0 = \frac{1}{4\pi} (2\pi \Delta P + \Delta P^2) \quad .$$

A more rigorous approach is to compute

$$\Delta A_0 = \int_0^{2\pi} \int_{r_2}^{r_2+u_r(r,\phi)} r \, dr \, d\phi$$

From strain displacement relations, we have (using cylindrical coordinates):

$$u_r(r_2,\phi) = r_2 \varepsilon_\phi(r_2,\phi) - \frac{\partial u_\phi(r_2,\phi)}{\partial \phi} \quad ,$$

where $u_r, u_\phi$ are radial and tangential displacements. It can be shown by eigenfunction expansions that the second term at the right of (20), for the present problem, is even in $\phi$ and periodic in $2\pi$.

Neglecting second order terms (linear elasticity), it is seen that this term makes no contribution to the integral in (19). Hence, essentially
we have $u_r(r_2, \phi) \equiv r_2 \epsilon_\phi(r_2, \phi)$ for the integration of (19). It was found that the evaluations of $\Delta \phi_0$, using the two methods, agree with each other to four significant figures.

For the data analysis, our choice of an angular function was an interpolating periodic cubic spline [4].

Definition of cubic spline:

Given an interval $\alpha < x < \beta$, (21)
a mesh on the interval,

$$\Delta : \quad \alpha = x_0 < x_1 < \ldots < x_N = \beta$$

and associated set of ordinates (data points),

$$Y : \quad y_0, y_1, \ldots, y_N$$

then the cubic spline satisfies:

$$S_\Delta(Y; x) \in C^2 \text{ on } [\alpha, \beta],$$

$$S_\Delta(Y, x_j) = y_j \quad (j=0, 1, \ldots, N)$$

and is coincident with a cubic on each interval,

$$x_{j-1} \leq x < x_j \quad (j=1, 2, \ldots, N)$$

If, in addition, the derivatives

$$S_\Delta(p)(\alpha^+) = S_\Delta(p)(\beta^-) \quad (p=0, 1, 2)$$

the spline is said to be periodic with period $(\beta-\alpha)$.

If alternatively

$$S_\Delta(Y; x_j) = y_j + \varepsilon_j \quad (j=0, 1, \ldots, N)$$

with the $\varepsilon_j$ subject to some minimizing constraint; it is said to be an approximating rather than interpolating spline.

As described in the previous section the data was taken at 14 angular position for six crack depths and at nine pressures. Discounting the data for crack depths greater than 2 in. (due to gage and tube failures) we have 756 data points for numerical analysis. To indicate the smooth nature of the strain data and interpolating functions we show in Figures 5a - 5e the results for various crack depths at 48,000 p.s.i.

Once the spline function has been found the changes in the cross-sectional area are computed by the methods indicated above. The partial results are presented in Table 2. It should be noted that the first row in Table 2, for zero crack depth, is not empirical data but extrapolated values and the set of data corresponding to starter notch (b=.25) have been eliminated. The stress intensity factors now have to be computed from (16)

\[
\frac{K_1}{p} = \left[ \frac{E}{2(1-\nu^2)} \frac{d(\Delta V_0/p)}{db} \right]^{1/2}, \text{ at } x_3=0, \quad (16)
\]

where \(\Delta V_0\) is the change in the outside volume of the cylinder per unit length at \(x_3=0\) and thus is numerically equivalent to \(\Delta A_0\) and also from

\[
\frac{K_1}{p} = \left[ \frac{E}{2(1-\nu^2)} \frac{d(\Delta V_0/p)}{db^*} \right]^{1/2}, \text{ at } x_3=0, \quad (28)
\]

where \(b^* = b + \frac{h}{2\pi} \left( \frac{K_1}{\sigma_y} \right)^{1/2} \) is an effective crack depth suggested by Irwin [5], \((0 \leq h \leq 1, \sigma_y = \text{yield stress}) \) to correct for the effect of plastic deformation at the crack boundary.

FIGURE 6. Comparison of stress intensity factors with (h=1) and without (h=0) Irwin correction for pressures at 40 and 48 ksi.
To compute the derivative of $\Delta V_0(b)$ we used a non-periodic approximating cubic spline with an algorithm which minimized

$$\int_0^b \{S^n(b)\} db + \lambda \sum_{i=1}^{n} \left\{S_i(b_i) - \Delta V_{0i}\right\}^2$$

(29)

where $\lambda$ is introduced to allow us to strike a balance between the amount of smoothing desired vs. maintaining the integrity of data. As seen from (28) we must of necessity evaluate $b^*$ and $K^*/p$, for a given value of $h$, by an iterative process which is stable. As a guide to selection of $\lambda$ we consider the type of $K_1$ expression common in fracture mechanics, $K_1 = \text{constant} \cdot b^{1/2}$ and see that $d^2K_1/db^2$ is strictly monotonic increasing. A value of $\lambda=10$ proved quite reasonable leading to a rapid and stable convergence of $K_1^*/p$.

The results of such an analysis for pressures of 40,000 and 48,000 psi are shown in Figure 6. In an ideal linear experiment $K_1/p$, for different pressure, should fall on the same curve. To partially account for plastic deformation at the crack surface we have incorporated the Irwin's correction term, as explained before. In Figure 6, we show the results for 48,000 and 40,000 psi without the Irwin-correction ($h=0$) and with correction ($h=1$). For clarity we have deleted the results for intermediate pressures and different values of $h$. In Figures 7, 8, and 9 we show the results for different pressures, and $h$. In all of these figures it is seen that the results are fairly close to each other.

**SECTION 4 - RESULTS BY COLLOCATION METHOD**

Because of the complexity in the geometry of the problem it seems that an analytic closed-form solution is not yet possible. However,

FIGURE 9c. Pressure decreased to 40 ksi.
FIGURE 9d. Pressure decreased to 32 ksi.
FIGURE 10. A rectangular block with a circular surface flaw is used to simulate a shallow surface crack in a thick-walled tube.
since we are working with relatively shallow surface cracks compared to the wall thickness of the tube (most of the fatigue life is confined to such crack growth as seen from Table 1) we can effectively simulate the curved surface of the tube by a rectangular block with a surface flaw in the form of a segment of a circle as shown in Figure 10 and apply the method of collocation. It is evident from Figures 3 and 4 that there is a 'shear lip' region extending radially to about 20° on either side of the inner wall of the tube. Hence the actual crack was simulated by a segment of a circle with a matching depth and the center having an offset d of .3(radius) of the circle as shown, i.e.(b=a+d). The thickness (TH) of the block was taken equal to the wall thickness (i.e. TH=R_0 - R_i) and it was found that it is sufficient to take half the width (HW) and half the height (HH) equal to three times the radius of the crack (HW=HH=3a). The loading condition on the block corresponds to the Lamé solution together with uniform tension due to the presence of pressure inside the crack:

\[
\sigma_z/p = 1 + \frac{1}{R_i^2} \left\{ \frac{R_i^2}{R_0^2} + \frac{R_i^2}{(R_i+d+x)^2} \right\}
\]

In the sequel, we give a brief outline of the exterior collocation method, the details can be found in [6].

---

The method of exterior collocation, for a symmetric surface flaw located on the plane \( z=0 \), requires construction of a set of functions which satisfy the mixed boundary conditions on the plane \( z=0 \). These conditions are: the normal stress is zero inside the crack-surface and normal displacement is zero outside the crack-surface. Symmetry of the problem further requires shearing stresses to vanish on the entire plane \( z=0 \). For the case of a circular flaw this was accomplished using three-dimensional Boussinesq potentials where the harmonic functions were represented by Kobayashi potentials (integral representation of potential functions) and superposition of such a solution with uniform field and plane strain solutions to satisfy the above boundary conditions. The results are:

\[
\sigma_r = \sum_n A_n (n(n+1)) r^{-2} [(1-2\nu) I_1 - z I_2] - (1-2\nu) I_5 - z I_6 \nonumber
\]

\[
-\epsilon_n a^{-n-3/2} (n-2)(2n+1) \Gamma(n+1/2) r^n /[4\nu \sqrt{\pi} \Gamma(n+1)] \cos \theta ,
\]

\[
\sigma_\theta = \sum_n A_n (-n(n+1)) r^{-2} [(1-2\nu) I_1 - z I_2] - 2\nu I_3 + r^{-1} [(1-2\nu) I_5 - z I_6] \nonumber
\]

\[
+ \epsilon_n a^{-n-3/2} (n+2)(2n+1) \Gamma(n+1/2) r^n /[4\nu \sqrt{\pi} \Gamma(n+1)] \cos \theta ,
\]

\[
\sigma_z = A_0 \sqrt{\pi} / 2 a^{-3/2} + \sum_n A_n (-I_3 - z I_4 + \epsilon_n a^{-n-3/2} (2n+1) \Gamma(n+1/2) r^n / \sqrt{2} \Gamma(n+1)] \cos \theta ,
\]

\[
\tau_{r\theta} = \sum_n \epsilon_n A_n (n(n+1)) r^{-2} [(1-2\nu) I_1 - z I_2] - n r^{-1} [(1-2\nu) I_5 - z I_6] \nonumber
\]

\[
+ a^{-n-3/2} (n+2)(2n+1) \Gamma(n+1/2) r^n /[4\nu \sqrt{\pi} \Gamma(n+1)] \sin \theta ,
\]

\[
\tau_{rz} = \sum_n A_n z [-n r^{-1} I_3 + I_7] \cos \theta ,
\]

\[
\tau_{\theta z} = \sum_n - \epsilon_n A_n n z r^{-1} I_3 \sin \theta .
\]

\[ (31) \]
Where \( \epsilon_n = 0 \) for \( n = 0 \), \( \epsilon_n = 1 \) for \( n \neq 0 \), the summation \( \sum \) is over \( n = 0, 1/2, 1, 3/2, \cdots, \infty \) and \( A_n \)'s are constants to be determined by the collocation method. We have used the cylindrical coordinate system \((r, \theta, z)\) with the origin located at the center of the circular crack of radius 'a', and \( I \)'s are integrals given below:

\[
I_1 = \int_0^\infty k^2 J_n(kr) J_{n+3/2}(ka) k^{1/2} e^{-zk} dk,
\]

\[
I_2 = -\alpha I_1/\alpha z, \quad I_3 = -\alpha I_2/\alpha z, \quad I_4 = -\alpha I_3/\alpha z
\]

and

\[
I_5 = \int_0^\infty k^{-1} J_{n-1}(kr) J_{n+3/2}(ka) k^{1/2} e^{-zk} dk
\]

\[
I_6 = -\alpha I_5/\alpha z, \quad I_7 = -\alpha I_6/\alpha z
\]

After some basic integration, it can be shown from (31) above,

\[
s_g(z=0) = \begin{cases} 
0 & , \quad r < a \\
\frac{A_0}{a^{3/2}} \sqrt{2} + \sum \frac{A_n}{r} \left[ \frac{2}{\sqrt{\pi}} r^{n+1} \right] \frac{1}{r} F(n+1, 1; n+\frac{3}{2}; \frac{a^2}{r^2}) \\
+ \frac{1}{r^{2}-a^2} \left[ \epsilon_n \right] \frac{(2n+1)^3 (\pi+1)}{\sqrt{2a^3} r (n+1)} \cos \theta, \quad r > a,
\end{cases}
\]

\[
2G_u(z=0) = \begin{cases} 
0 & , \quad \text{for } r > a \\
2\sqrt{2/\pi} (1-\nu) a^{-3/2}(a^2-r^2)^{1/2} \sum A_n (r/a)^n \cos \theta, \quad r < a.
\end{cases}
\]

Hence it is seen from (33), (34) that the set of functions selected satisfy the mixed boundary conditions of the crack problem. The stress intensity factor can be computed from equation (34) or (35):

39

\[ K_1 = K_1(\theta) = \sqrt{2} a^{-1} \sum_n A_n \cos n \theta \] (36)

Once the \( A_n \)'s have been computed.

In general it is not possible to obtain \( A_n \)'s in the infinite series. An approximate solution, however, can be found by satisfying boundary conditions at \( m \) selected discrete points, called collocation points, on the remaining boundaries exterior to the plane of the crack. At each boundary point there are three boundary conditions. From the \( 3m \) equations we can at most solve for \( 3m \) unknown coefficients \( A_n \)'s. To avoid an illconditioned matrix, the boundary conditions are to be satisfied in a least square sense. Computationally, the least square procedure, in obtaining stable results, is to choose a rather large value of \( m \) and solve \( A_n \)'s from the \( N \times N \) system of 'normal equations', which are derived by minimizing the sum of the squares of errors at collocation points. Since the value of \( N \) is not known a priori, we solve the normal equations for \( N=1, 2, \ldots \) until the required stability is achieved in \( K_1 \) and there is no significant change in 'residuals'. As explained in [6] there is an additional requirement for surface flaw problems; namely the boundary traction must vanish at points of the crack-free surface intersection. This gives a linear constraint on \( A_n \)'s (see Table 3) and leads to zero stress intensity factors at such points. With \( TH, HH, HW, a, d, v, N \), Figure 10, as input parameters and automatic generation of \( m \) nearly equally spaced collocation points, a computer program was

FIGURE 11: Graph of $K_d/p$ vs $N$ showing the stability of collocation results for $|\nu|\leq 15$.
FIGURE 12. Graph of $K_1/p$ vs $\theta$ for $N=28$ with 109 collocation points.
FIGURE 13. Graph of $K_1/p$ vs $b$, obtained by compliance tests and collocation method for non-autofrettage tube.
written which calculates $A_n$'s and the stress intensity factors as briefly described. (The symmetry of the problem allows us to work with half of the geometry.)

In Figure 11, we plot $K_1/p$ vs $N$, up to $N=35$, showing the stability of the results. It is seen that the results are stable within 3-4% for $N>15$. In Figure 12, we plot $K_1/p$ vs $\theta$ for $N=28$ with 109 collocation points. It is seen that $K_1/p$ is maximum at $\theta=0$ (i.e. at the deepest point of the crack) and vanishes at $\theta=107.46^\circ$ (i.e. at points of the crack-free surface intersection). In Table 3, we list $A_n$'s for the above case showing convergences of $A_n$ for large $n$. Similar computations were carried out for crack depths of $b=a+d = .1, .2, .3, .4, .5, .75, 1.0, 1.3$ and 2. inches. The results are shown in Figure 13. In the same figure, we have plotted $K_1/p$ obtained by compliance results (see Figure 9). Excellent agreement is seen between the experimental and theoretical results.

CONCLUDING REMARKS

In this report we have developed a compliance calibration of a thick-walled circular cylinder with a symmetric internal surface flaw. Results obtained agree well, for small crack depths, to those obtained analytically for a semi-circular flaw by the collocation method.
REFERENCES

APPENDIX A

A collocation analysis for simulated crack geometry was also carried out for the case of an autofrettaged tube. Due to the presence of compressive stress at the inner bore of the tube, it was reasonable to assume the loading condition as a superposition of applied and the residual stress fields. Hence, eq (30) was replaced by:

\[
\frac{\sigma_z}{p} = 1 + \frac{1}{(1-a^2/b^2)} \left( \frac{a^2}{b^2} + \frac{a^2}{(a+d+x)^2} \right)
\]

\[
\left\{ \begin{array}{l}
\frac{c_y}{p\sqrt{3}} \left[ (2 \log \frac{(a+d+x)+b^2}{\rho}-\frac{a^2}{b^2})\frac{a^2}{(a+d+x)^2} \right] (2 \log \frac{p+1}{a^2/b^2})/(1-a^2/b^2), \\
\frac{a^2}{b^2}+a^2/(a+d+x)^2)/(1-a^2/b^2)
\end{array} \right.
\]

for \((a+d+x)\leq \rho\) \hspace{1cm} (A-1) \hspace{1cm} for \((a+d+x)\geq \rho\)

where \(a=R_i\), \(b=R_o\), are the inner and outer radii. \(\sigma_y\) the yield stress, \(p\) is the pressure and \(\rho\) is the interface depending upon the percentage of autofretting (e.g., for 30% autofrettage \(\rho = a + 0.3(b-a)\).) The results of such a computation for \(R_i = 3.55''\) \(R_o = 7.125''\) \(p = 48,000\) psi, \(\sigma_y = 170,000\) psi, and crack depths \(b = 0.125'', 0.25'', 0.5'', 0.75'', 0.9'', 1'', 1.25'', 1.5'', 1.75'', 2''\) are plotted in Figure A1. It is seen that \(K_I/p\) is substantially lower for an autofrettaged tube as compared to a non-autofrettaged tube (Fig. 13). It is further seen that \(\frac{aK_I/p}{a^b}\) is bounded as opposed to a non-autofrettaged tube at \(b = 0\).

The compliance test as previously explained was done for a 30% autofrettaged tube of the same dimensions as before. The change in the

</table>
cross-sectional area was computed as before and the results for a few pressures are given in Table A1. It is immediately seen that the data is quite scattered for small crack depths. This may be due to the fact that the notch was put in before the autofrettage process or may be due to relaxation of residual stresses under cyclic loading in the presence of a notch. Neglecting the first three data points and extrapolating the data for zero crack depth to $\Delta A_0 = 0.357\text{in}^2$ the stress intensity factors with $h=1.0$ and $\lambda=1000$ (less smoothing) were computed. The results are shown in Figure A1, together with the collocation data. Again, fairly good agreement is seen for small crack depths.
