We consider a regular Markov process with continuous parameter, countable state space, and stationary transition probabilities, over which we define a class of traffic processes. The feasibility that multiple traffic processes constitute mutually independent Poisson processes is investigated in some detail.

We show that a variety of independence conditions on the traffic process and the underlying Markov process are equivalent or sufficient to ensure Poisson related properties; these conditions include independent increments.
renewal, weak pointwise independence, and pointwise independence. Two computational criteria for Poisson traffic are developed: a necessary condition in terms of weak pointwise independence, and a sufficient condition in terms of pointwise independence. The utility of these criteria is demonstrated by sample applications to queueing-theoretic models.

It follows that, for the class of traffic processes as per this paper in a queueing-theoretic context, Kelly's notion of quasi-reversibility and Gelenbe and Muntz's notion of completeness are essentially equivalent to pointwise independence of traffic and state. The latter concept, however, is the most general one. The relevance of the theory developed to queueing network decomposition is also pointed out.
Abstract

We consider a regular Markov process with continuous parameter, countable state space, and stationary transition probabilities, over which we define a class of traffic processes. The feasibility that multiple traffic processes constitute mutually independent Poisson processes is investigated in some detail.

We show that a variety of independence conditions on the traffic process and the underlying Markov process are equivalent or sufficient to ensure Poisson related properties; these conditions include independent increments, renewal, weak pointwise independence and pointwise independence. Two computational criteria for Poisson traffic are developed: a necessary condition in terms of weak pointwise independence, and a sufficient condition in terms of pointwise independence. The utility of these criteria is demonstrated by sample applications to queueing-theoretic models.

It follows that, for the class of traffic process as per this paper in a queueing-theoretic context, Kelly's notion of quasi-reversibility and Gelenbe and Muntz's notion of completeness are essentially equivalent to pointwise independence of traffic and state. The latter concept, however, is the most general one. The relevance of the theory developed to queueing network decomposition is also pointed out.

1. Introduction

This paper has grown out of previous work on traffic in certain queueing networks ([4],[14],[15]) whose state process is a discrete state Markov process. The paper generalizes several aspects of the discussion and results in the papers alluded to above. In particular, a general notion of a traffic process over a discrete state Markov process will be defined and the feasibility of it being a Poisson process will be investigated. We shall also exemplify the utility of the results by applying them to a number of queueing models.

In the way of motivation, we point out that traffic processes in networks with flow characteristics (e.g. queueing networks, communication networks, machine repair shops, etc.) are an important operating characteristic of such models. They are also of major importance to the study of valid decompositions of such networks. It is common to postulate, in such models, that the incoming traffic is a Poisson process, a fact that often renders a mathematical analysis tractable; it is also based on many real-life empirical data. If, in addition, one may validly assume that traffic flows within the network are also Poisson processes, then this could give rise to decompositions of the original network such that each component subnetwork may be validly studied in isolation ([4],[14]).

The treatment of traffic processes in this paper will, however, be more general—at the level of Markov processes.
2. Traffic Processes over a Discrete State Markov Process

Throughout the paper, \( \{C(t)\}_{t \geq a} \) will designate a right-continuous Markov process with parameter set \([a, \infty)\) for some real \(a\), and a countable state set \(\Gamma\). We assume \( \{C(t)\}_{t \geq a} \) to have standard and stationary transition probabilities, so that the associated infinitesimal generator matrix \(Q\) is time homogenous; its transition rate elements are denoted \(q(y, \delta), \; y, \delta \in \Gamma\). We shall further assume that \(q(y) \triangleq \sum_{\delta \in \Gamma \setminus \{y\}} q(y, \delta) < \infty\) for all \(y \in \Gamma\), and that the \(q(y)\) are bounded as \(y\) ranges over \(\Gamma\). Thus the process \( \{C(t)\}_{t \geq a} \) is regular in the sense of Cinlar [6] p. 251.

Our assumptions on \( \{C(t)\}_{t \geq a} \) imply that the associated Forward and Backward Kolmogorov Equations have unique and identical solutions for the transition probabilities ([9] p. 475).

Denoting \(P_{t}(y) \triangleq P[C(t) = y]\) and premultiplying the matrix form of the Forward Equations (cf. [8] pp. 240-241) by a row vector initial condition with components \(P_{a}(y)\) yields a system of equations in the absolute state probabilities

\[
\frac{\partial}{\partial t} P_{t}(y) = \sum_{\xi \in \Gamma \setminus \{y\}} P_{t}(\xi)q(\xi, y) - P_{t}(y)q(y), \; t \geq a, \; y \in \Gamma. \tag{2.1}
\]

We shall say that equilibrium prevails if \( \{C(t)\}_{t \geq a} \) is in steady state; equivalently, in equilibrium, \(\frac{\partial}{\partial t} P_{t}(y) = 0, \; t \geq a\), for all \(y \in \Gamma\).

Next, let \(\Theta : \{\{(y, \gamma) : y \in \Gamma\}\} \) be an arbitrary set of pairs of distinct states. To avoid trivialities we shall always assume that \(\Theta \neq \emptyset\).

For each \(y \in \Gamma\), \(\Theta\) gives rise to the following sets \(\Theta(y, \cdot) \triangleq \{\delta : (y, \delta) \in \Theta\}\) and \(\Theta(\cdot, y) \triangleq \{\beta : (\beta, y) \in \Theta\}\).

Consider the sequence of epochs \(\{T_{n}\}_{n=0}^{\infty}\) where
3

\[ T_n = \begin{cases} 
0, & \text{if } n=0 \\
\inf \{ t : t > T_{n-1}, (C(t^-), C(t^+)) \in \Gamma \}, & \text{if } n>0 
\end{cases} \]

induced by \( \Gamma \).

Thus, \( T_n \) is the epoch of the \( n \)-th occurrence of a jump in \( \{C(t)\}_{t \geq a} \) from some \( \gamma \in \Gamma \) to some \( \delta \in \Gamma \) such that \( (\gamma, \delta) \in \Omega \). We adopt here the view that certain state transitions in the underlying \( \{C(t)\}_{t \geq a} \) are interpreted as traffic due to entities (customers, messages etc.) moving about in the system.

Instead of studying the traffic point process \( \{T_n\}_{n=0}^\infty \), one may equivalently elect to study the traffic interval process \( \{T_{n+1} - T_n\}_{n=0}^\infty \), or equivalently again the traffic counting process \( \{K(t)\}_{t \geq a} \) defined by

\[ K(t) = \begin{cases} 
0, & \text{if } t=a \\
k, & \text{if } T_k \leq t < T_{k+1} 
\end{cases} \]

The state space of \( \{K(t)\}_{t \geq a} \) is \( \mathbb{N} \cup \{0\} \) where \( \mathbb{N} \) is the set of natural numbers.

In this paper, we shall adopt the following terminology.

**Definition 2.1**

A traffic process over \( \{C(t)\}_{t \geq a} \) is a process \( \{K(t)\}_{t \geq a} \) induced by some \( \Omega \in \mathbb{R}^2 \) as described above. The inducing \( \Omega \) will henceforth be referred to as a traffic set.

The particular choice of the representation of a traffic process is a mere technical convenience serving the purposes of this paper. It is simply due to the fact that a Poisson process can be represented as a counting process whose state probabilities satisfy a simple system of
birth equations.

What can be said about the joint process \((C(t), K(t))\) for \(t \geq a\)? First we show (cf. [4], Theorem 1).

**Lemma 2.1**

The joint process \((C(t), K(t))\) for \(t \geq a\) is a conservative Markov process with bounded transition rates.

**Proof**

The jumps of \(K(t)\) for \(t \geq a\) are contained in those of \(C(t)\) for \(t \geq a\). Therefore, the joint process is conservative, since \(C(t)\) for \(t \geq a\) is. Moreover, the jumps of \(C(t)\) for \(t \geq a\) uniquely determine those of \(K(t)\) for \(t \geq a\). Hence for every \(s < u\), \(K(u) - K(s)\) is measurable with respect to the \(\sigma\)-algebra \(\sigma(C(t): s < t < u)\) generated by \(C(t)\) for \(s < t < u\). Let \(t_1 < t_2 < \ldots < t_r < u\) be a partition of the interval \([a, u]\). Then, for any \(\gamma_j \in \Gamma\), \(k_j \in \mathbb{N} \cup \{0\}\), \(1 \leq j \leq r\),

\[
P[C(u) = \gamma, K(u) = k | \bigcap_{j=1}^{r} (C(t_j) = \gamma_j, K(t_j) = k_j)]
\]

\[
= P[C(u) = \gamma, K(u) - K(t_r) = k - k_r | \bigcap_{j=1}^{r} (C(t_j) = \gamma_j, K(t_j) = k_j)].
\]

But \([K(u) - K(t_r) = k - k_r] \in \sigma(C(t): t_r < t < u)\) while \(\bigcap_{j=1}^{r} (K(t_j) = k_j) \in \sigma(C(t): a < t < t_r)\).

By the Markov property of \(C(t)\) for \(t \geq a\), the previous equation evaluates to

\[
P[C(u) = \gamma, K(u) - K(t_r) = k - k_r | C(t_r) = \gamma_r, K_{t_r} = k_r]
\]

\[
= P[C(u) = \gamma, K(u) = k | C(t_r) = \gamma_r, K_{t_r} = k_r]
\]

which verifies the requisite Markov property of the process \((C(t), K(t))\) for \(t \geq a\). Finally, boundedness of the transition rates of the joint process follows from the fact that they have the form
\[ q((y,k),(\delta,\xi)) = \begin{cases} 
q(y,\delta), & \text{if } (y,\delta) \notin \emptyset \text{ and } 0 \leq k = \xi - 1 \\
q(y,\delta), & \text{if } (y,\delta) \notin \emptyset \text{ and } k = \xi \\
0, & \text{otherwise} 
\end{cases} \quad (2.2) \]

Denoting \( P_t(y,k) \equiv P[C(t)=y,K(t)=k] \) and with the aid of (2.2), we can now derive the equations in the absolute state probabilities for \( \{C(t),K(t)\}_{t \geq a} \), analogously to the ones previously derived for \( \{C(t)\}_{t \geq a} \).

\[ \frac{\partial}{\partial t} P_t(y,k) = \sum_{\xi \notin \emptyset \setminus \{y\}} P_t(\xi,k)q(\xi,y) + \sum_{\xi \notin \emptyset \setminus \{y\}} P_t(\xi,k-1)q(\xi,y) 
- P_t(y,k)q(y), \quad t \geq a, \quad (y,k) \in \Gamma \times (\emptyset \cup \{0\}). \quad (2.3) \]

The initial conditions are

\[ P_a(y,k) = \begin{cases} 
P_a(y), & \text{if } k = 0 \\
0, & \text{otherwise} 
\end{cases} \quad (2.4) \]

since \( K(a) = 0 \) almost surely.

Eq. (2.3) can be equivalently written as

\[ \frac{\partial}{\partial t} P_t(y,k) = \sum_{\xi \notin \emptyset \setminus \{y\}} P_t(\xi,k)q(\xi,y) - P_t(y,k)q(y) 
+ \sum_{n \in \emptyset \setminus \{y\}} (P_t(n,k-1) - P_t(n,k))q(n,y), \quad t \geq a, \quad (y,k) \in \Gamma \times (\emptyset \cup \{0\}), \quad (2.5) \]

by adding and subtracting \( \sum_{n \in \emptyset \setminus \{y\}} P_t(n,k)q(n,y) \) from Eq. (2.3).
Finally, denoting \( P_t(k) = P[K(t)=k] \) and summing Eq. (2.5) over \( \gamma \in \Gamma \) gives us

\[
\frac{\partial}{\partial t} P_t(k) = \sum_{\gamma \in \Gamma} \sum_{\eta \in O(\cdot, \gamma)} (P_t(\eta, k-1) - P_t(\eta, k)) q(\eta, \gamma),
\]

\( t > a, k \in \mathbb{N} \cup \{0\} \). (2.6)

To interchange summation and differentiation in the above we have used the fact that the \( P_t(\gamma, k) \) have derivatives of every order in \( t \), and that every countable sum of the \( P_t(\gamma, k) \) over a subset of \( \Gamma \times (\mathbb{N} \cup \{0\}) \) is uniformly convergent on each compact time interval of \([a, \infty)\). This fact will henceforth justify all termwise operations on sums of the \( P_t(\gamma, k) \) such as termwise integration, differentiation etc. ([17], 1.1, 1.7).

Throughout the paper we denote \( M(t) \triangleq E[K(t)] \). To avoid trivialities we shall, henceforth, restrict the discussion to substantive traffic processes in the following sense.

**Definition 2.2**

A traffic process is nontrivial if \( M(t) \neq 0 \), \( t > a \); otherwise it is trivial.

We now show

**Theorem 2.1**

\[
M(t) = \sum_{\gamma \in \Gamma} \sum_{\eta \in O(\cdot, \gamma)} q(\eta, \gamma) \int_{a}^{t} P_{\tau}(\eta) d\tau, \ t > a .
\]

(2.7)

**Proof**

For every fixed \( n \in \mathbb{N} \) sum (2.6) over \( k \geq n \); then integrate both sides of the resultant sum thus obtaining
\[ \mathbb{E}[K(t) \geq n] = \sum_{Y \in \Gamma} \sum_{\eta \in \Theta(Y)} q(\eta, Y) \int_{a}^{t} P_{t}(\eta, n-1) d\tau, \quad t \geq a. \]

Eq. (2.7) now follows by summing the above over \( n \in \mathbb{N} \), since \( \{K(t)\}_{t \geq a} \) is a non-negative integer valued random variable.

**Corollary 2.1**

\[ M(t) \equiv \lambda t, \quad t \geq 0, \text{ for some } \lambda \geq 0 \text{ iff } \]

\[ \sum_{Y \in \Gamma} \sum_{\eta \in \Theta(Y)} P_{t}(\eta)q(\eta, Y) \equiv \text{const.}, \quad t \geq a. \]

In particular, \( M(t) \equiv \lambda t, \quad t \geq a, \) in equilibrium.
3. Poisson Traffic Processes

In this section we shall give a number of simple characterizations of Poisson related traffic processes over a Markovian process. We shall see that only a subset of the ordinary Poisson axioms will here suffice.

To simplify notation we shall henceforth denote

\[ m(t) \overset{\triangle}{=} \sum_{\gamma \in \Gamma} \sum_{\eta \in \Theta(\gamma, \gamma')} P_t(\eta)q(\eta, \gamma) = \frac{\partial}{\partial t} M(t) \text{ and } m(t, \gamma) \overset{\triangle}{=} \sum_{\eta \in \Theta(\gamma, \gamma')} P_t(\eta)q(\eta, \gamma). \]

Intuitively, \( m(t) \) is the total rate of expected traffic count, while \( m(t, \gamma) \) is the rate of expected traffic count due to transitions into state \( \gamma \).

Observe that \( m(t) = \sum_{\gamma \in \Gamma} m(t, \gamma) \) and that in equilibrium both \( m(t) \) and \( m(t, \gamma) \) are independent of \( t \).

The first theorem characterizes an arbitrary Poisson process over \( \{C(t)\}_{t \geq a} \).

**Theorem 3.1**

\( \{K(t)\}_{t \geq a} \) is a Poisson process iff \( \{K(t)\}_{t \geq a} \) has independent increments.

**Proof**

(\( \Rightarrow \)) If \( \{K(t)\}_{t \geq a} \) is a Poisson process, then it has independent increments by definition.

(\( \Leftarrow \)) Suppose \( \{K(t)\}_{t \geq a} \) has independent increments. It remains to show that each \( K(t) \), \( t \geq a \), is Poisson distributed. Let \( \phi_t(y) \) be the generating function of \( K(t) \), and \( \phi_{s, t}(y) \) that of \( K(t) - K(s) \). Then

\[ \phi_{t+\varepsilon}(y) = \phi_t(y) \cdot \phi_{t, t+\varepsilon}(y), \quad t \geq a, \varepsilon > 0, |y| \leq 1. \]

Differentiating the above with respect to \( \varepsilon \) and sending \( \varepsilon \to 0 \) yields

\[ \frac{\partial}{\partial \varepsilon} \phi_t(y) = \phi_t(y) \cdot \frac{\partial}{\partial t} \phi_{t, t}(y), \quad t \geq a, |y| \leq 1. \quad (3.1) \]

Next, denote \( P_{s, t}(y, k) \overset{\triangle}{=} P[C(t) = y, K(t) - K(s) = k] \) and \( P_{s, t}(k) \overset{\triangle}{=} P[K(t) - K(s) = k] \). The process \( \{(C(t), K(t) - K(s))\}_{t \geq s} \) is a
Markov process for any fixed $s \geq a$, by appeal to Lemma 2.1. Moreover, Eq. (2.5) still holds with $P_{s,t}(\gamma, k)$ substituted throughout for $P_t(\gamma, k)$. Thus, the analogue of Eq. (2.6) with $s=t$ becomes

$$\frac{\partial}{\partial t} P_{t,t}(k) = \sum_{\gamma \in \Gamma} \sum_{\eta \in \Omega(\gamma)} (P_{t,t}(\eta, k-1) - P_{t,t}(\eta, k))q(\eta, \gamma)$$

whence

$$\frac{\partial}{\partial t} \phi_{t,t}(y) = m(t)(y-1).$$

In view of the initial condition (2.4), the unique solution to Eq. (3.1) is $\phi_t(y) = \exp(M(t)(y-1))$ which corresponds to a Poisson distributed process with respective parameters $M(t)$.

The second theorem characterizes a time homogenous Poisson process over $\{C(t)\}_{t \geq a}$.

**Theorem 3.2**

$\{K(t)\}_{t \geq a}$ is a time homogenous Poisson process iff the following conditions hold:

i) $\{T_n\}_{n=0}^\infty$ is a renewal process

ii) $m(t) \equiv m(a)$, $t \geq a$.

**Proof**

$(\implies)$ If $\{K(t)\}_{t \geq a}$ is a time homogenous Poisson process then it is well-known that $\{T_n\}_{n=0}^\infty$ is a renewal process. Furthermore, the rate of $\{K(t)\}_{t \geq a}$ is $\frac{\partial}{\partial t} M(t) = m(t) \equiv m(a)$, $t \geq a$, as required, due to Corollary 2.1.

$(\impliedby)$ Conversely, suppose that i) and ii) hold. Since the renewal function $R(t)$ of $\{T_n\}_{n=0}^\infty$ is $R(t) = M(t) = \int_0^t m(\tau)d\tau = m(a)t$, it follows that $\{K(t)\}_{t \geq a}$ must be a time homogenous Poisson process, as $R(t)$ determines...
a renewal process.

Corollary 3.1

In equilibrium, the renewal process property of \( \{T_n\}_{n=0}^{\infty} \) is equivalent to the Poisson process property of \( \{K(t)\}_{t \geq a} \).

The preceding characterizations give us some information as regards non-Poisson traffic processes, by way of elimination.

Corollary 3.2

Suppose \( \{K(t)\}_{t \geq a} \) is not a Poisson process. Then \( \{K(t)\}_{t \geq a} \) does not have independent increments, and, in equilibrium, the respective point process \( \{T_n\}_{n=0}^{\infty} \) is not even a renewal process (though it may be a delayed renewal process).
4. Multiple Traffic Processes over a Discrete State Markov Process

Let \( \{K_1(t)\}_{t \geq a}, \ldots, \{K_n(t)\}_{t \geq a} \) be traffic processes over \( \{C(t)\}_{t \geq a} \), for some fixed but arbitrary \( n \in \mathbb{N} \). For the \( i \)-th traffic process above, the associated entities are denoted \( O_i \) for its traffic set, \( M_i(t) \) for its mean function etc.; in general, we append the appropriate index to such previously defined symbols. To simplify notation we shall denote in the sequel \( K(t) \triangleq (K_1(t), \ldots, K_n(t)) \) to be the vector traffic process, and \( k \triangleq (k_1, \ldots, k_n) \) to be a vector with non-negative integer components.

**Lemma 4.1**

The joint process \( \{(C(t); K_1(t), \ldots, K_n(t))\}_{t \geq a} \) is a conservative Markov process with bounded transition rates.

**Proof**

With the previous redefinitions of the symbols \( K(t) \) and \( k \), the proof of Lemma 3.1 goes through mutatis mutandis for Lemma 4.1.

The transition rates of the joint process are

\[
q((\gamma, \delta), (\gamma', \delta')) = \begin{cases} 
q(\gamma, \delta), & \text{if } (\gamma, \delta) \in \bigcup_{i=1}^{n} O_i \text{ and } 0 \leq k = \sum_{i=1}^{n} x_i(\gamma, \delta)e_i \\
q(\gamma, \delta), & \text{if } (\gamma, \delta) \notin \bigcup_{i=1}^{n} O_i \text{ and } k=\ell \\
0, & \text{otherwise}
\end{cases}
\]

for \( (\gamma, \delta), (\gamma', \delta') \in \Gamma \times (\mathbb{N} \cup \{0\})^n \); in the above \( x_i \) is the characteristic function

\[
x_i(\gamma, \delta) = \begin{cases} 
1, & \text{if } (\gamma, \delta) \in O_i \\
0, & \text{otherwise}
\end{cases}
\]

and \( e_i \) is the \( n \)-dimensional unit vector with 1 in the \( i \)-th coordinate.

\[\square\]
The counterpart of Eq. (2.5) for the joint process 
\{\{C(t), K_1(t), \ldots, K_n(t)\} \}_{t \geq a} is

\[
\frac{\partial}{\partial t} P_t(y, k) = \sum_{\xi \in \Gamma - \{y\}} P_t(\xi, k)q(\xi, y) - P_t(y, k)q(y) + \sum_{i=1}^{n} \sum_{n \in \bigcup_{i=1}^{m} O_i \setminus \{\cdot, y\}} (P_t(n, k - e_i) - P_t(n, k))q(n, y) \quad (4.2)
\]

for \( t \geq a \), \((y, k) \in \Gamma \times (N \cup \{0\})^n \).

For reasons that will become apparent later on, we shall restrict the discussion to traffic processes which are disjoint in the following sense.

**Definition 4.1**

\( \{K_1(t)\}_{t \geq a}, \ldots, \{K_n(t)\}_{t \geq a} \) are said to be **disjoint traffic processes** if their associated traffic sets \( O_1, \ldots, O_n \) are disjoint sets.

For disjoint traffic processes, Eq. (4.2) reduces to

\[
\frac{\partial}{\partial t} P_t(y, k) = \sum_{\xi \in \Gamma - \{y\}} P_t(\xi, k)q(\xi, y) - P_t(y, k)q(y) + \sum_{i=1}^{n} \sum_{n \in O_i \setminus \{\cdot, y\}} (P_t(n, k - e_i) - P_t(n, k))q(n, y), \quad (4.3)
\]

for \( t \geq a \), \((y, k) \in \Gamma \times (N \cup \{0\})^n \).

The initial condition becomes

\[
P_a(y, k) = \begin{cases} 
P_a(y), & \text{if } \sum_{i=1}^{n} k_i = 0 \\ 0, & \text{otherwise} \end{cases} \quad (4.4)
\]
The counterpart of Eq. (2.6) is obtained by summing Eq. (4.3) over $\gamma \in \Gamma$ thus yielding

$$\frac{\partial}{\partial t} P_t(k) = \sum_{i=1}^{n} \sum_{\gamma \in \Gamma} \sum_{\eta \in O_i} \left( P_t(n, k-e_i) - P_t(n, k) \right) q(\eta, \gamma),$$

for $t \geq a$, $k \in (N \cup \{0\})^n$.  

(4.5)
5. Multiple Disjoint Poisson Traffic Processes

In this section we investigate the possibility that disjoint multiple traffic processes \( \{K_1(t)\}_{t \geq a}, \ldots, \{K_n(t)\}_{t \geq a} \) have Poisson related properties. In particular, the upcoming discussion applies to single traffic processes as the special case \( n = 1 \).

**Definition 5.1**

The processes \( \{C(t)\}_{t \geq a}, \{K_1(t)\}_{t \geq a}, \ldots, \{K_n(t)\}_{t \geq a} \) are said to be pointwise independent if for every \( t \geq a \) the random variables \( C(t), K_1(t), \ldots, K_n(t) \) are mutually independent. The processes above are said to be weakly pointwise independent if for every \( t \geq a \) and every \( (k_1, \ldots, k_n) \in (\mathbb{N} \cup \{0\})^n \),

\[
\sum_{i=1}^{n} \sum_{y \in i \in \mathbb{N} \cup \{0\}} \sum_{y = 0}^{t} P_t(n, k_1, \ldots, k_n)q(n, y) = \sum_{i=1}^{n} \sum_{y \in i \in \mathbb{N} \cup \{0\}} \sum_{y = 0}^{t} P_t(n)(\prod_{j=1}^{n} P_t(k_j))q(n, y).
\] (5.1)

Since pointwise independence is of central interest here, the disjointness assumption is necessary so as not to preclude it a priori.

We begin, however, with a characterization of weak pointwise independence.

**Theorem 5.1**

\( K_1(t), \ldots, K_n(t) \) have mutually independent Poisson distributions for every \( t \geq a \) iff \( \{C(t)\}_{t \geq a}, \{K_1(t)\}_{t \geq a}, \ldots, \{K_n(t)\}_{t \geq a} \) are weakly pointwise independent processes.

**Proof**

(\( \Rightarrow \)) Suppose the \( K_i(t), 1 \leq i \leq n \), are distributed as mutually independent Poissons. Then the generating function of \( K(t) \) is
\[ \phi_t(y_1, \ldots, y_n) = \exp \left( \sum_{i=1}^{n} M_i(t)(y_i-1) \right), \quad t \geq a, \quad |y_i| \leq 1, \quad 1 \leq i \leq n, \quad (5.2) \]

whence
\[ \frac{\partial}{\partial t} \phi_t(y_1, \ldots, y_n) = \phi_t(y_1, \ldots, y_n) \sum_{i=1}^{n} m_i(t)(y_i-1), \quad t \geq a, \quad |y_i| \leq 1, \quad 1 \leq i \leq n. \quad (5.3) \]

On equating coefficients in (5.3) we obtain
\[ \frac{\partial}{\partial t} P_t(k) = \sum_{i=1}^{n} (P_t(k-e_i) - P_t(k)) m_i(t) \]
\[ = \sum_{i=1}^{n} \left( \prod_{j=1}^{n} P_t(k_j-\delta_{ji}) - \prod_{j=1}^{n} P_t(k_j) \right) \sum_{\gamma \in \Gamma} \sum_{n \in \mathbb{Z}_+^n} \sum_{\nu \in \mathbb{Z}_+^n} P_t(n) q(n, \gamma) \quad (5.4) \]
\[ t \geq a, \quad k=(k_1, \ldots, k_n) \in \mathbb{N}_0^n \]

where \( \delta_{ji} \) is Kronecker's delta.

Eq. (5.1) now follows by equating the right side of Eq. (5.4) to the right side of Eq. (4.5), via a straightforward multiple induction on \( k=(k_1, \ldots, k_n) \).

(\( \Rightarrow \)) Assume that Eq. (5.1) holds. Substituting (5.1) into (4.5) and rearranging terms in the resultant equation yields Eq. (5.4). The latter is equivalent to Eq. (5.3) whose unique solution is given by Eq. (5.2), since the initial condition is \( \phi_a(y_1, \ldots, y_n) = 1, \quad |y_i| \leq 1, \quad 1 \leq i \leq n, \) by virtue of (4.4).

Consequently, \( P_t(k) \) corresponds to \( n \) Poisson-distributed processes with respective rates \( m_i(t) \); moreover, the \( K_i(t) \) are mutually independent for every \( t \geq a \).
Corollary 5.1

If \( \{C(t)\}_{t \geq a} \) is in equilibrium and \( \{K(t)\}_{t \geq a} \) is a singleton (\( n=1 \)) Poisson traffic process over it, then

\[
\sum_{\gamma \in \Gamma} \sum_{\eta \in \mathbb{N} \setminus \{0\}} \frac{\partial}{\partial t} p_t(n, k) q(\eta, \gamma) = (m(t))^{\eta+1} p_t(k) \\
= (m(a))^{\eta+1} \exp(-m(a)t) \frac{(m(a)t)^{k}}{k!}, \quad t \geq a
\]

for any \( \eta, k \in \mathbb{N} \setminus \{0\} \).

Next we characterize pointwise independence of traffic and state.

Theorem 5.2

\( \{C(t)\}_{t \geq a}, \{K_1(t)\}_{t \geq a}, \ldots, \{K_n(t)\}_{t \geq a} \) are pointwise independent processes iff

\[
\sum_{i=1}^{n} m_i(t, \gamma) = p_t(\gamma) \sum_{i=1}^{n} m_i(t), \quad t \geq a, \text{ for every } \gamma \in \Gamma.
\]  

(5.5)

Proof

(\( \Rightarrow \)) Suppose pointwise independence holds. Eq. (4.3) is equivalent to the generating function equation

\[
\frac{\partial}{\partial t} [p_t(\gamma) \phi_t(y_1, \ldots, y_n)] \\
= \sum_{\xi \in \Gamma - \{\gamma\}} p_t(\xi) \phi_t(y_1, \ldots, y_n) q(\xi, \gamma) - p_t(\gamma) \phi_t(y_1, \ldots, y_n) q(\gamma) \\
+ \sum_{i=1}^{n} \sum_{\eta \in \mathbb{N} \setminus \{0\}} p_t(\eta) \phi_t(y_1, \ldots, y_n) (y_i - 1) q(\eta, \gamma)
\]

(5.6)

\( t \geq a, \ |y_i| \leq 1, \ 1 \leq i \leq n, \ \gamma \in \Gamma \),

where \( \phi_t(y_1, \ldots, y_n) = \exp(\sum_{i=1}^{n} M_i(t)(y_i - 1)) \) is the generating function of \( K(t) \) due to Theorem 5.1. We use this form of \( \phi_t(y_1, \ldots, y_n) \) in differentiating the left side of (5.6) which after some manipulation becomes
\[ \frac{\partial}{\partial t} [P_t(y) \phi_t(y_1, \ldots, y_n)] = \phi_t(y_1, \ldots, y_n) \left( \frac{\partial}{\partial t} D_t(y) + P_t(y) \sum_{i=1}^{n} m_i(t)(y_i-1) \right). \]

Since \( \phi_t(y_1, \ldots, y_n) \) may be cancelled on both sides of (5.6), the latter reduces to

\[ \frac{\partial}{\partial t} P_t(y) + P_t(y) \sum_{i=1}^{n} m_i(t)(y_i-1) = \frac{\partial}{\partial t} P_t(y) + \sum_{i=1}^{n} m_i(t,y)(y_i-1). \] (5.7)

Eq. (5.5) now follows from the above by equating the relevant coefficients.

\( \Rightarrow \) Suppose Eq. (5.5) holds. It can be checked directly that

\[ P_t(y,k_1, \ldots, k_n) = \begin{cases} \frac{\sum_{i=1}^{n} m_i(t,y)}{\sum_{i=1}^{n} m_i(t)} \frac{\prod_{j=1}^{n} \exp(-M(t))}{M_i(t)^{k_j} k_j!} \quad & \text{if } \sum_{i=1}^{n} m_i(t)>0 \\ 0, & \text{otherwise} \end{cases} \] (5.8)

solves Eq. (4.3) and is consistent with the initial condition (4.4).

An easy proof of this assertion involves the transformation of (5.8) into the appropriate \( P_t(y) \phi_t(y_1, \ldots, y_n) \) and then working the way backwards from (5.7) to (5.6) which is equivalent to (4.3).

**Corollary 5.2**

a) \( \{C(t)\}_{t \geq a}, \{K_1(t)\}_{t \geq a}, \ldots, \{K_n(t)\}_{t \geq a} \) are mutually pointwise independent iff \( \{C(t)\}_{t \geq a} \) and \( \{K_i(t)\}_{t \geq a} \) are pointwise independent in pairs for every \( 1 \leq i \leq n \).

b) Eq. (5.5) holds iff for every \( 1 \leq i \leq n \),

\[ m_i(t,y) = P_t(y)L_i(t), \quad t \geq a, \quad y \in \Gamma, \]

for some functions \( L_i(t) \) depending on \( t \) only; in fact for every \( 1 \leq i \leq n \), \( L_i(t) = m_i(t), \quad t \geq a, \) necessarily.
c) Consequently, in equilibrium, Eq. (5.5) holds iff for every $1 \leq i \leq n$, $m_i(t, \gamma) = P_t(\gamma)L_i$, $t \geq a$, $\gamma \in \Gamma$, for some constants $L_i$; in fact for every $1 \leq i \leq n$, $L_i = m_i$.

Proof

a) Mutual pointwise independence implies pointwise independence in pairs. Conversely, pointwise independence in pairs implies for every $1 \leq i < n$, $m_i(t, \gamma) = P_t(\gamma)m_i(t)$, $t \geq a$, $\gamma \in \Gamma$. This becomes Eq. (5.5) on summing both sides over $1 \leq i \leq n$.

b) If Eq. (5.5) holds, then from a) the condition holds for $L_i(t) \equiv m_i(t)$. Conversely, by summing both sides of $m_i(t, \gamma) = P_t(\gamma)L_i(t)$ over $\gamma \in \Gamma$ we deduce $L_i(t) \equiv m_i(t)$; summing it over $1 \leq i \leq n$ then yields Eq. (5.5).

c) Follows immediately from b) and from the time stationarity of the $m_i(t, \gamma)$ and $m_i(t)$.

The relation of Eq. (5.5) and parts a) and c) in Corollary 5.2 to Gelenbe and Muntz ([10], p. 53) should be noted. A more detailed discussion, however, is deferred until Sec. 8.

Before proceeding to the main theorem we shall now prove two supporting lemmas. The first one is a generalization of Corollary 1 in [4].

Lemma 5.1

$\{C(t)\}_{t \geq a}$ and the multiple traffic process $\{K(t)\}_{t \geq a}$ are pointwise independent iff for any fixed $s \geq a$, $\{C(t)\}_{t \geq s}$ and $\{K(t) - K(s)\}_{t \geq s}$ are pointwise independent.

Proof

$(\Leftarrow)$ Follows immediately by taking $s = a$. 
(⇒ ) Since \( \{C(t)\}_{t \geq s} \) is a Markov process, it follows from Lemma 2.1 that \( \{(C(t), K(t)-K(s))\}_{t \geq s} \) is also Markovian. To distinguish between \( \{(C(t), K(t))\}_{t \geq a} \) and \( \{(C(t), K(t)-K(s))\}_{t \geq s} \) we denote the various mathematical entities associated with the latter by appending tildas to the corresponding ones in the former.

Thus, Eq. (4.3) is satisfied by \( \tilde{P}_t(\gamma, k) \) over the domain \( t \in [s, \omega) \), subject to the initial condition (4.4) with \( a = s \). Since \( \tilde{P}_t(\gamma) = P_t(\gamma) \) for every \( \gamma \in \Gamma \) and \( t \geq s \), it also follows that \( \tilde{m}_i(\gamma, t) = m_i(\gamma, t) \) and \( \tilde{m}_i(t) = m_i(t) \) for any \( t \geq s \), \( 1 \leq i \leq n \) and \( \gamma \in \Gamma \).

Now, by pointwise independence of \( \{C(t)\}_{t \geq a} \) and \( \{K(t)\}_{t \geq a} \), Eq. (5.5) holds, whence

\[
\sum_{i=1}^{n} \tilde{m}_i(t, \gamma) = \tilde{P}_t(\gamma) \sum_{i=1}^{n} \tilde{m}_i(t), \quad t \geq s, \quad \gamma \in \Gamma,
\]

also holds. The Lemma now follows from (5.9) by applying Theorem 5.2 in the other direction.

The second lemma is tantamount to Burke's argument in [5]. (See also Theorem 3 in [4]).

Lemma 5.2

Suppose that \( \{C(t)\}_{t \geq a} \) and the multiple traffic process \( \{K(t)\}_{t \geq a} \) are pointwise independent. Then, for every fixed \( t \geq a \), the \( \sigma \)-algebras

\( \sigma(K(t)-K(s):s \leq t) \) and \( \sigma(C(u), K(u)-K(t):u \geq t) \) are independent.

Proof

Recall that whenever \( t_1 < t_2 \), \( \sigma(K(t_2)-K(t_1)) \subseteq \sigma(C(t):t_1 < t \leq t_2) \). Let \( \Lambda \subseteq \sigma(C(u), K(u)-K(t):u \geq t) \setminus \sigma(C(t):u \geq t) \). By the Markov property of \( \{C(t)\}_{t \geq a} \) we can write for any \( s \leq t \), \( \gamma \in \Gamma \) and \( k \in NU(0) \):
\[ P[A|C(t)=y, K(t)-K(s)=k] = P[A|C(t)=y] \]

Now, from the above and Lemma 5.1,

\[ P[A, C(t)=y, K(t)-K(s)=k] \]

\[ = P[A|C(t)=y, K(t)-K(s)=k] \cdot P[C(t)=y, K(t)-K(s)=k] \]

\[ = P[A|C(t)=y] \cdot P[C(t)=y] \cdot P[K(t)-K(s)=k] \]

\[ = P[A, C(t)=y] \cdot P[K(t)-K(s)=k] \]

whence on summing both sides above over \( y \in \Gamma \),

\[ P[A, K(t)-K(s)=k] = P[A] \cdot P[K(t)-K(s)=k] \]  \hspace{1cm} (5.10) 

as required.

**Corollary 5.3**

If \( \{C(t)\}_{t \geq a} \) and \( \{K(t)\}_{t \geq a} \) are pointwise independent processes, then from Lemma 5.2 each \( \{K_i(t)\}_{t \geq a}, 1 \leq i \leq n \), has independent increments; consequently, each is a Poisson process by combining Theorem 5.1 and Lemma 5.2.

We shall now proceed to show a stronger independence result, (cf. Theorem 4 in [4]).

**Theorem 5.3**

Suppose \( \{C(t)\}_{t \geq a} \) and the multiple traffic process \( \{K(t)\}_{t \geq a} \) are pointwise independent processes. Then the component traffic processes \( \{K_1(t)\}_{t \geq a}, \ldots, \{K_n(t)\}_{t \geq a} \) are mutually independent Poisson processes.

**Proof**

In view of Corollary 5.3 it suffices to show that for each partition
a = t_0 < t_1 < t_2 < \ldots < t_r = t \text{ of an arbitrary interval } [a,t], \text{ and for any choice of non-negative integers } k_{ij}, 1 \leq i \leq n, 1 \leq j \leq r, \text{ the events}

\begin{align*}
E_{i,j} \triangleq [K_i(t_j) - K_i(t_{j-1}) = k_{ij}], \quad 1 \leq i \leq n, 1 \leq j \leq r,
\end{align*}

are mutually independent. The proof is by induction on r.

If r=1, then the E_{i,r} are mutually independent by pointwise independence among the \(\{K_i(t)\}_{t \geq a}\), and the induction base is established.

Assume now that the Theorem holds for r=k, k \geq 1, and show it for r=k+1. Since \(\bigcap_{i=1}^{n} \bigcap_{j=1}^{r} E_{i,j} \subset \{K(t_{k+1}) - K(s) : s \leq t_k\}\) and

\[\Lambda \triangleq \bigcup_{i=1}^{n} \bigcap_{j=1}^{k+1} \{C(u), K(u) - K(t_{k+1}) : u \geq t_k\},\]

we can write by virtue of Lemma 5.2,

\[P[\bigcap_{i=1}^{n} \bigcap_{j=1}^{k+1} E_{i,j}] = P[\bigcap_{i=1}^{n} \bigcap_{j=1}^{k} E_{i,j}] P[\bigcap_{i=1}^{n} E_{i,k+1}]\]

Finally, applying the induction hypothesis to the first factor above and Lemma 5.1 to the second factor yields

\[P[\bigcap_{i=1}^{n} \bigcap_{j=1}^{k+1} E_{i,j}] = \prod_{i=1}^{n} \prod_{j=1}^{k+1} P[E_{i,j}]\]

which establishes the induction step.

In view of Theorem 5.3, we now see that Theorem 5.2 provides us with a computational criterion as follows.

**Corollary 5.4**

If Eq. (5.5) holds, then the \(\{K_i(t)\}_{t \geq a}, 1 \leq i \leq n\), are mutually independent Poisson processes with respective rate functions \(m_i(t), t \geq a\).
Applications of the theory developed thus far are furnished in the next two sections.
6. Atomic Traffic Processes

Consider the class of traffic processes defined by

Definition 6.1

\( \{K(t)\}_{t \geq a} \) is called an atomic traffic process if its traffic set is a singleton pair of states.

Atomic traffic processes are the elementary building blocks of all traffic processes, since every traffic process is a superposition of disjoint traffic atoms.

We shall now exemplify the utility of the weak pointwise independence concept vis-a-vis atomic traffic processes.

First, however, we show a more general result.

Lemma 6.1

Let \( \{K(t)\}_{t \geq a} \) be a non-trivial traffic process such that

\[
( \bigcup_{\xi \in \Gamma} \theta(\cdot, \xi)) \cap (\bigcup_{\xi \in \Gamma} \theta(\xi, \cdot)) = \emptyset.
\]

Then \( \{K(t)\}_{t \geq a} \) is not a time homogenous Poisson process; moreover, in equilibrium it is not a Poisson process altogether.

Proof

Setting \( k=0 \) and letting \( t \to a^+ \) in Eq. (2.5) gives us

\[
\frac{3}{\partial t} P_a(\gamma,0) = \frac{3}{\partial t} P_a(\gamma) - m(a,\gamma), \quad \gamma \in \Gamma.
\]

If \( \theta(\cdot, \gamma) = 0 \) for some \( \gamma \in \Gamma \), then \( \theta(\cdot, \eta) = \emptyset \) by (6.1) so that \( m(a,\eta) = 0 \).

Hence

\[
\frac{3}{\partial t} P_a(\eta,0) = \frac{3}{\partial t} P_a(\eta) \quad \text{for any } \eta \in \theta(\cdot, \gamma), \gamma \in \Gamma.
\]
Substituting the above into the left side of (5.1) for \( n=1 \) and differentiating yields for \( t+a^+ \)

\[
\sum_{\gamma \in \mathcal{E}} \sum_{n \in \mathcal{O}(\gamma)} \frac{3}{\partial t} P_{\alpha}(n,0)q(n,\gamma) = \sum_{\gamma \in \mathcal{E}} \sum_{n \in \mathcal{O}(\gamma)} \frac{3}{\partial t} P_{\alpha}(n,0)q(n,\gamma) = \frac{3}{\partial t} m(a). \tag{6.2}
\]

Now assume \( \{K(t)\}_{t \geq a} \) is a Poisson process. By weak pointwise independence of \( \{C(t)\}_{t \geq a} \) and \( \{K(t)\}_{t \geq a} \) (see Theorem 5.1)

\[
\sum_{\gamma \in \mathcal{E}} \sum_{n \in \mathcal{O}(\gamma)} \frac{3}{\partial t} P_{\alpha}(n,0)q(n,\gamma) = \lim_{t \to a^+} \frac{3}{\partial t} [m(t) \cdot \exp(-M(t))] \\
= \lim_{t \to a^+} [m(t) \cdot \exp(-M(t)) \cdot (-m(t)) + \exp(-M(t)) \cdot \frac{3}{\partial t} m(t)] = \frac{3}{\partial t} m(a) - (m(a))^2. \tag{6.3}
\]

A comparison of (6.2) and (6.3) gives us necessarily \( m(a) = 0 \). But if \( \{K(t)\}_{t \geq a} \) is time homogenous, then \( m(t) \equiv 0 \) from ii) in Theorem 3.2, which contradicts the nontriviality of \( \{K(t)\}_{t \geq a} \). Finally, in equilibrium, \( \{K(t)\}_{t \geq a} \) is necessarily time homogenous from Corollary 2.1, whence the rest of the Theorem follows.

We can now assert,

**Corollary 6.1**

None of the nontrivial atomic traffic processes over \( \{C(t)\}_{t \geq a} \) is a time homogenous Poisson process. Furthermore, in equilibrium, none is a Poisson process.

**Proof**

The Corollary follows trivially since every singleton traffic set \( \{C_{(a,b)} \} \) satisfies Eq. (6.1).

Thus, in equilibrium, we have the intuitively curious situation...
where none of the nontrivial traffic atoms is a Poisson process; however, an arbitrary superposition of traffic atoms may or may not be a Poisson process. In fact, examples of both cases abound in the queueing-theoretic literature (see next section).

We point out that if a superposition of point processes forms a Poisson process, then either all superposed components are independent Poisson processes or none is. Most superposition results are variants of the first type (see e.g. Çinlar [7]). What we have just shown is a nonvacuous example that falls within the scope of the second type.

To further illustrate the utility of Corollary 6.1 we note that the departure process (exclusive of the loss stream) from an M/M/1/0 queue in equilibrium is not a Poisson process. In the same spirit we can deduce that any departure stream of customers from a Markovian queueing network, such that departing customers leave behind a prescribed network state, cannot be a Poisson process in equilibrium.
7. Queueing-Theoretic Examples

In this section we demonstrate how to apply pointwise independence to certain traffic processes in a number of queueing networks whose discrete state is represented by a Markov process. These applications utilize the computational criterion of Theorem 5.2 as set forth in Corollary 5.4.

Example 7.1: Jackson queueing networks (see Jackson [11]).

A Jackson network consists of $J$ service stations with infinite line capacities. Each station $j$ houses $s_j$ parallel independent exponential servers with respective rates $\sigma_j$. Exogenous customers arrive at the stations according to independent Poisson processes with respective rates $\alpha_j$. On service completion at station $j$ a customer is routed to station $k, 0 < k < J$, with probability $p_{jk}$ (a routing to $k=0$ designates leaving the network altogether). All arrival, service, and routing processes are mutually independent.

The vector valued process of the $J$ line sizes is a Markov process with state space $\Gamma = \{\gamma = (n_1, \ldots, n_J) : n_j \in \mathbb{N} \cup \{0\}\}$. Next, suppose the equations

$$
\delta_j = \alpha_j + \sum_{j=1}^{J} \delta_i p_{ij}, \ 1 \leq j \leq J,
$$

have a non-negative solution in the $\delta_j, 1 \leq j \leq J$. This is always the case when the network is open in the sense that it is possible to leave the network from every node through some finite sequence of routings (see [14], Ch. 4).

Suppose the network is open such that $\rho_j \triangleq \delta_j / \sigma_j s_j < 1, 1 \leq j \leq J$. Then the state equilibrium distribution is $P_t(n_1, \ldots, n_J) \equiv \prod_{j=1}^{J} P_t(n_j)$ where
Let \( \{K_j(t)\}_{t \geq a} \) be the equilibrium traffic process of customers that leave the network from station \( j \). Thus \( \theta_j = \{(\gamma + e_j, \gamma) : \gamma \in \Gamma \} \) and \( \theta_j(\cdot, \gamma) = \{\gamma + e_j\} \).

Denoting \( \sigma_j(\varepsilon) \triangleq \min\{\varepsilon, s_j\} \sigma_j \), we compute for any \( \gamma = (n_1, ..., n_J) \in \Gamma 
\)
\[
m_j(t, \gamma) \equiv P_t(\gamma + e_j) \sigma_j(n_j + 1)p_{j0}
\]
\[
= P_t(\gamma) \frac{\rho_j}{\min(n_j + 1, s_j)} \sigma_j(n_j + 1)p_{j0}
\]
\[
= P_t(\gamma) \delta_j p_{j0} = P_t(\gamma) \delta_j p_{j0}, \quad 1 \leq j \leq J.
\]

Hence, part c) of Corollary 5.2 holds for \( L_j = \delta_j p_{j0}, \quad 1 \leq j \leq J \).

It now follows from Corollary 5.4 that the \( \{K_j(t)\}_{t \geq a}, \quad 1 \leq j \leq J \), are mutually independent Poisson processes with respective rates \( \delta_j p_{j0} \), provided the network is in equilibrium.

We point out that this result includes as a special case the well-known result by P.J. Burke \([5]\) that the equilibrium departure process from a M/M/s queue is a Poisson process with the same rate as the arrival process; this result was arrived at by examining the inter-departure intervals. The same result was later attained by E. Reich \([16]\) through the use of reversibility. A related derivation was demonstrated by F.P. Kelly \([12]\) via the concept of quasi-reversibility (see \([13]\)) which is itself related to pointwise independence (see Section 8).
Kelly's results apply to a wide class of Markovian queueing networks to be described in the sequel.

Example 7.2: Kelly's networks with random routings (see Kelly [12]).

In this queueing model we have J service stations with infinite waiting line capacities and I types of customers. Exogenous customers type 1, \(1 \leq i \leq I\), arrive at station \(j, 1 \leq j \leq J\), according to independent Poisson processes with respective rates \(\alpha_j(i)\). Each station \(j\) houses an exponential server with rate \(\sigma_j \phi_j(n_j)\), where \(n_j\) is the total number of customers at station \(j\). The routing probabilities \(p_{jk}(i)\) depend on the type of customer routed. In addition, the \(\ell\)-th customer in line \(j\) is allocated a proportion \(f_j(\ell, n_j)\) of the service effort in station \(j\). A customer arriving at station \(j\) is inserted in the \(\ell\)-th position there with probability \(g_{j}(\ell, n_j + 1)\). All arrival, service and routing processes are mutually independent. The vector-valued process of line configurations is a Markov process with state space \(\Gamma=\{(c_1, \ldots, c_J) : c_j \in \mathcal{I}^*\}\) where \(\mathcal{I}^*\) is the set of all finite strings \(c_j(1)c_j(2)\ldots c_j(n_j)\) where \(c_j(\ell)\) is the type of the \(\ell\)-th customer in station \(j\) (\(\mathcal{I}^*\) includes the empty string). The transition rates of the state process are defined by

\[
q(y, T_{j,k}(\gamma)) = \sigma_j \phi_j(n_j) p_{jk}(c_j(\ell)) f_j(\ell, n_j)
\]

\[
q(y, T_{j,\ell}(\gamma)) = \alpha_j(i) g_j(\ell, n_j + 1)
\]

\[
q(y, T_{jk|m}(\gamma)) = \sigma_j \phi_j(n_j) p_{jk}(c_j(\ell)) f_j(\ell, n_j) g_k(m, n_k + 1)
\]

where \(T_{j,\ell}\) is the operator that removes the \(\ell\)-th customer at station \(j\) from the network; \(T_{j,\ell}^i\) is the operator that inserts a customer of type \(i\) in the \(\ell\)-th position at station \(j\); \(T_{jk|m}\) is the operator that moves the \(\ell\)-th customer in station \(j\) to the \(m\)-th position in station \(k\).
When the network is open with respect to every customer type $i$, $1 \leq i \leq I$, Eq. (7.1) has unique solutions $\delta_j(i)$ for $\alpha_j = a_j(i)$ and $p_{jk} = p_{jk}(i)$, $1 \leq j, k \leq J$, and we denote $\rho_j(i) = \frac{\delta_j(i)}{\sigma_j}$. Under certain conditions (see Theorem 2, ibid.) the equilibrium distribution has the form

$$P_t(c_1, \ldots, c_J) \equiv b \prod_{j=1}^{J} A_j(c_j) \tag{7.2}$$

where $b$ is a positive constant and

$$A_j(c_j) = \begin{cases} \frac{\prod_{k=1}^{n_j} \rho_j(c_j(k))}{\phi_j(k)}, & \text{if } n_j \geq 1 \\ 1, & \text{otherwise} \end{cases}$$

Let $\{K_{ij}(t)\}_{t \geq a}$ be the equilibrium traffic process of customers type $i$ which depart the network from station $j$. Thus, $O_{ij} = \{T^i_{j.\lambda}(\gamma), \gamma \in \Gamma, 1 \leq \lambda \leq n_j + 1\}$ and $\Theta_{ij}(\cdot, \cdot, \cdot) = \{T^i_{j.\lambda}(\gamma): 1 \leq \lambda \leq n_j + 1\}$.

For any $\gamma = (c_1, \ldots, c_J) \in \Gamma$ we now compute using the identity

$$P_t(T^i_{j.\lambda}(\gamma)) = P_t(\gamma) \frac{\rho_j(i)}{\phi_j(n_j + 1)},$$

$$m_{ij}(t, \gamma) = \sum_{\lambda=1}^{n_j + 1} P_t(T^i_{j.\lambda}(\gamma)) q(T^i_{j.\lambda}(\gamma), \gamma)$$

$$= \sum_{\lambda=1}^{n_j + 1} P_t(\gamma) \frac{\rho_j(i)}{\phi_j(n_j + 1)} q(T^i_{j.\lambda}(\gamma), T_{j.\lambda}(T^i_{j.\lambda}(\gamma)))$$

$$= P_t(\gamma) \sum_{\lambda=1}^{n_j + 1} \frac{\delta_j(i)}{\sigma_j \phi_j(n_j + 1)} \theta_j(\gamma)(\sigma_j \phi_j(n_j + 1) p_j(0(i) f_j(\lambda, n_j + 1))$$

$$= P_t(\gamma) \delta_j(i) p_j(0(i), 1 \leq i \leq I, 1 \leq j \leq J.$$
Example 7.3: Kelly's networks with fixed routes and gamma-distributed service (see Kelly [13]).

This model is a variation on the basic setup of J stations and I types of customers, where we conveniently take \( a_j = 1, \ 1 \leq j \leq J \). For \( 1 \leq i \leq I \), customers type \( i \) arrive according to mutual independent Poisson processes with respective rates \( \alpha(i) \). A customer traces a fixed route \( r(i,1), r(i,2), \ldots, r(i,S(i)) \) of \( S(i) \) stages through the network and then exits. At node \( r(i,s) \) on the route, a customer requires a gamma distributed (Erlang) service composed of \( z(i,s) \) phases of mutually independent exponential services each with mean \( d(i,s) \). We require, however, that \( \frac{\alpha(i)}{\delta_j} \geq g_j \) for all \( 1 \leq j \leq J \). All arrival and service processes are mutually independent.

The state process is Markovian over the state space \( \Gamma \) consisting of all \( J \)-tuples \( \gamma = (c_1, \ldots, c_J) \) where each \( c_j \) is a finite (possibly empty) string over the alphabet \( \{(i,s,p): 1 \leq i \leq I, 1 \leq s \leq S(i), 1 \leq p \leq z(i,s)\} \). Define

\[
\delta_j(i,s) = \alpha(i)d(i,s)\delta_j, r(i,s), \ 1 \leq j \leq J, 1 \leq i \leq I, 1 \leq s \leq S(i),
\]

where \( \delta_j, r(i,s) \) is Kronecker's delta.

Under certain conditions, the equilibrium state distribution is again given by Eq. (7.2) provided we redefine

\[
A_j(c_j) = \begin{cases} 
\frac{n_j \delta_j(t_j(\lambda), s_j(\lambda))}{\phi_j(\lambda)}, & \text{if } n_j > 0 \\
1, & \text{otherwise}
\end{cases} \tag{7.3}
\]

where \( t_j(\lambda) \) and \( s_j(\lambda) \) are the type and stage respectively of the \( \lambda \)-th customer in line configuration \( c_j \), and \( n_j \) is the length of \( c_j \).

Let the \( \{K_{ij}(t)\}_{t \geq a} \) be as in the previous example. Thus,
Here $T^{C}_{j,k}$ is the operator that inserts a customer with attribute set $c$ as above (i.e. a customer type $i$ in his last stage of the route and last phase in service) into the $k$-th position in station $j$. Observing $\lambda_j(i, S(i))$ that $P_t(T^{C}_{j,k}(\gamma)) = P_t(\gamma) \frac{\delta_j(i, S(i))}{\phi_j(n_j + 1)}$ we compute

$$m_{ij}(t, \gamma) = \sum_{k=1}^{n_j + 1} P_t(T^{C}_{j,k}(\gamma)) q(T^{C}_{j,k}(\gamma), \gamma) = P_t(\gamma) \sum_{k=1}^{n_j + 1} \frac{\delta_j(i, S(i))}{\phi_j(n_j + 1)} f_j(\gamma, n_j + 1)$$

$$= P_t(\gamma) \delta_j(i, S(i)), 1 \leq i \leq l, 1 \leq j \leq J.$$

We conclude that the $\{K_{ij}(t)\}_{t \geq 0}$ are mutually independent Poisson processes with respective rates $\delta_j(i, S(i))$.

Analogous results can be similarly obtained for the class of Kelly's networks in Sec. 3 of [13] where the $f_j$ are allowed to differ from the $g_j$, but the service requirements are constrained to be exponential.

Suppose the rate of type $i$ arrivals is $\alpha(i, \gamma)$; i.e. it is also a function of the instantaneous state of the system. Kelly ([13], Sec. 5) considers the case $\alpha(i, \gamma) = \alpha(i) \cdot \prod_{W \omega \in \gamma} \psi(H(\gamma, W))$, where $\psi : \mathbb{N} \cup \{0\} \to [0, \infty)$ is a given function, and $H(\gamma, W) = \sum_{i=1}^{m} H(\gamma, i)$ where $H(\gamma, i)$ is the number of type $i$ customers in network configuration $\gamma$. He shows that under certain conditions the equilibrium state distribution has the form

$$P_t(\gamma) = b \cdot B(\gamma) \cdot \prod_{j=1}^{J} A_j(c_j) \quad (7.4)$$
where

\[
B(y) = \prod_{Wc2} H(y,W) - 1 \prod_{n=0} \psi(n) \tag{7.5}
\]

and the \(A_j(c_j)\) are still defined by (7.3). Thus, in the notation of Example 7.3, \(B(T_C^C, j, y(y)) = B(y) \prod_{W:i \in W} \psi(H(y,W))\) for any \(c = (i, S(i), z(i, S(i)))\), whence

\[
P_t(T_C^C, j, y(y)) = P_t(y) \cdot (\prod_{W:i \in W} \psi(H(y,W))) \cdot \frac{\delta_j(i, S(i))}{\phi_j(n_j+1)}.
\]

It follows in an analogous calculation that

\[
m_{ij}(t,y) = P_t(y) \delta_j(i, S(i)) \cdot \prod_{W:i \in W} \psi(H(y,W)).
\]

Hence, \(\{C(t)\}_{t \geq a}\) and \(\{K_{ij}(t)\}_{t \geq a}\) are pointwise independent iff \(\prod_{W:i \in W} \psi(H(y,W)) = L^1\) independent of \(y \in \Gamma\), which is generally not the case.

Notice, however, that when the product above does depend on \(y \in \Gamma\), this does not, in general, exclude \(\{K_{ij}(t)\}_{t \geq a}\) from being a Poisson process, albeit pointwise dependent on the state. A similar phenomenon takes place in the following.

Example 7.4: The BCMP queueing networks (see Baskett et. al. [2]).

These networks consist of four types of stations, all related to Kelly's networks in [12]. There are, however, three differences: customers arrive according to state dependent Poisson processes; they require type dependent services which are mixtures of sums of exponentials; and on service completion customers are allowed to change types.

†A typical case in point is an arrival process to a Jackson network which is Poisson by definition. However, it can be easily verified that it is pointwise dependent on the state, say in equilibrium.
in a Markovian manner.

Based on the equilibrium state distributions derived in [2], it can be rigorously shown that the $m_{ij}(t)$ factor into $P_t(\gamma)$ and another product. The latter contains the instantaneous arrival rate as a state dependent factor. Consequently, the $\{K_{ij}(t)\}_{t \geq a}$ and $\{C(t)\}_{t \geq a}$ are not, in general, pointwise independent when the network is in equilibrium. However, it can be rigorously checked that the above are pointwise independent provided the arrival rates are fixed. The latter fact agrees with Theorem 13 in [10].

The author is unaware of any result in the queueing-theoretic literature annunciating Poisson departure traffic processes (over a discrete state Markov process) that cannot be explained by means of pointwise independence of traffic count and state.
8. Discussion

The class of intuitive traffic processes that can be modeled via distinguished state transitions in the underlying process \( \{C(t)\}_{t \geq a} \) is fairly comprehensive vis-a-vis applications. In particular it includes all traffic processes in the queueing-theoretic literature with the exception of certain feedback traffic processes. In a typical situation (see e.g. [14] and [15]) one starts out with a set of "generating" processes \( \{G(t)\}_{t \geq a} \) (arrivals, services and routings) which give rise to a "state" process \( \{C(t)\}_{t \geq a} \) in the sense that the latter is measurable with respect to the \( \sigma \)-algebra generated by the former.

Consider a feedback stream of customers that after service completion in station \( j \) immediately rejoin the waiting line to that station in such a way that the state of the system remains unchanged (notice that this situation never arises for traffic processes between distinct nodes or for traffic streams that leave the network altogether). In other words, we need the concept of a transition from a state to itself, complete with transition rates \( 0 < q(\gamma, \gamma) < \infty \). While this does not affect Eq. (2.1) (observe that \( P_t(\gamma)q(\gamma, \gamma) \) cancels out since it appears with different signs in the two summations), defining the relevant \( \{T_n\}_{n=0}^{\infty} \) becomes impossible since a consideration of any traffic set \( \emptyset \) is insufficient to determine the epochs in question. Moreover, a direct appeal to Lemma 2.1 is now invalid, even though the result of the Lemma may be correct.

To remedy this situation one may attempt to proceed in two ways. First, it may be possible to modify \( \{C(t)\}_{t \geq a} \) into a new Markov process \( \{\tilde{C}(t)\}_{t \geq a} \) with state space \( \tilde{\Gamma} \) for which all feedback epochs correspond to discernible state transitions. The second approach is to define directly
the requisite joint process \(((C(t),K(t)))_{t>a}\) in terms of the "generating" processes and to show it to be Markovian by another technique (e.g. via a stochastic integral representation as in [14] and [3]). Either way, chances are that the rest of the theory in this paper would still be applicable, as was the case in [14] and [15].

A broader class of traffic processes over Markovian processes \(\{C(t)\}_{t>a}\) may be defined by allowing the traffic epochs \(\{T_n\}_{n=0}^\infty\) to be affected by past history of \(\{C(t)\}_{t>a}\). More accurately, the decision whether \(t=T_n(\omega)\) for some \(n\) (here \(\omega\) is a sample point), would require knowledge of the sample path \(\{C(t,\omega)\}_{a\leq t\leq T}\) or even that of the sample generating process \(\{G(t,\omega)\}_{a\leq t\leq T}\); it could not be effected on the basis of the pair \((C(I_-,\omega),C(I_+,\omega))\) alone by predicing the decision on whether or not that pair is in some traffic set \(\emptyset\).

To remedy this situation, one may again attempt to redefine a Markovian "state" process \(\tilde{C}(t)\) with a modified state space \(\Gamma\) in such a way that \(\{C(t)\}_{t>a}\) "remembers by state" the relevant information in the past history of the old \(\{C(t)\}_{t>a}\) so that the aforesaid decision as regards \(I\) and \(\omega\) can be made on the basis of \((C(I_-,\omega),C(I_+,\omega))\) and its relation to some \(\widehat{\emptyset}\) alone.

The approach and definitions of this paper shed a new light on the differential equations (2.1). The traditional heuristic interpretation is that the "probability rate of being in state \(\gamma\)" is the difference between the "flow rate into \(\gamma\)" and "the flow rate out of \(\gamma\)". On the other hand, let \(\Omega_\gamma =\{(\xi,\gamma):\xi\in\Gamma-\gamma\}\) and \(\Omega_\gamma =\{(\gamma,\xi):\xi\in\Gamma-\gamma\}\). Then clearly for any \(\gamma\in\Gamma\),

\[
\frac{\partial}{\partial t} P_t(\gamma) = m_\gamma(t) - m_\gamma(t),
\]

or equivalently upon integration

\[
P_t(\gamma) = P_\gamma(\gamma) + E[K_{\gamma}(t) - K_{\gamma}(t)],
\]

\(t>a\).
From this equation it can be easily shown that for any $s \leq t$

$$P_t(\gamma) - P_s(\gamma) = E[K_{\gamma \text{in}}(s,t) - K_{\gamma \text{out}}(s,t)]$$

where $K(s,t) \equiv K(t) - K(s)$.

Thus, from a traffic oriented vantage point the probability difference of being in state $\gamma$ at the extreme points of any time interval $[s,t]$ equals the expected difference of the number of times the system entered and left state $\gamma$ in the aforesaid interval.

It is interesting to note how the Markov property of the underlying ${C(t)}_{t \geq a}$ affects the feasibility of ${K(t)}_{t \geq a}$ being a Poisson related process. It turns out that various notions of independence play a significant role in this respect: independent increments in ${K(t)}_{t \geq a}$ already ensure it to be a Poisson process (Theorem 3.1); a renewal ${T_n}_{n=0}^\infty$ and a time invariant $m(t)$ already ensure the same thing (Theorem 3.2); weak pointwise independence already ensures that disjoint $K_1(t), \ldots, K_n(t), t \geq a$, are distributed as mutually independent Poissons (Theorem 5.1); and finally pointwise independence already ensures that disjoint ${K_1(t)}_{t \geq a}, \ldots, {K_n(t)}_{t \geq a}$ are mutually independent Poisson processes (Theorem 5.3).

The relation of pointwise independence of ${C(t)}_{t \geq a}$ and ${K(t)}_{t \geq a}$ to Kelly's notion of quasi-reversibility should be noted. In Sec. 6 of [13], Kelly describes a queueing network with Poisson arrivals; the network is represented by a Markov state process ${C(t)}_{t \geq a}$ in equilibrium, and each departing customer is classified into one of $I$ groups depending (perhaps stochastically) on the network's past history. Such a queue is quasi-reversible if (see p. 428 ibid.):

(a) departures of group $i$ customers, for $i=1,2,\ldots, I$, form independent
Poisson processes; and
(b) the state of the network at time \( t \) is independent of departures from the network up until time \( t \).

Suppose the \( I \) departure streams can be modeled by traffic processes \( \{K_1(t)\}_{t \geq a}, \ldots, \{K_I(t)\}_{t \geq a} \) via traffic sets \( O_i, 1 \leq i \leq I \). Then quasi-reversibility clearly implies pointwise independence of \( \{C(t)\}_{t \geq a} \) and the \( \{K_i(t)\}_{t \geq a}, 1 \leq i \leq I \), (Condition (b) above). However, Theorem 5.3 shows that pointwise independence of \( \{C(t)\}_{t \geq a} \) and the \( \{K_i(t)\}_{t \geq a}, 1 \leq i \leq I \), already implies Condition (a) above (i.e. (b) implies (a)). It follows that for the class of departure processes defined as traffic processes in the sense of this paper, quasi-reversibility is logically equivalent to pointwise independence (i.e. to Condition (b) alone).

In Sec. 5 of [10], Gelenbe and Muntz discuss Markovian queue with Poisson arrivals at a fixed rate \( \lambda \); they define such systems to be complete (ibid. p. 52) if the departure process \( \{K(t)\}_{t \geq a} \) satisfies

\[
\lim_{t \to \infty} P[K(t) - K(t-\Delta t) = i|C(t) = y] = \begin{cases} 
\lambda \Delta t + o(\Delta t), & \text{if } i = 1 \\
o(\Delta t), & \text{if } i \geq 1 \\
1 - \lambda \Delta t + o(\Delta t), & \text{if } i = 0
\end{cases}
\]

for any \( y \in \Gamma \).

Then, they proceed to give a heuristic derivation of equilibrium analogues of Corollary 5.2. By virtue of Lemma 5.1, we can recognize completeness as pointwise independence of \( \{C(t)\}_{t \geq a} \) and \( \{K(t)\}_{t \geq a} \) when the former is in equilibrium. As a matter of fact, for the class of traffic processes in this paper over an underlying \( \{C(t)\}_{t \geq a} \) in equilibrium, Kelly's quasi-reversibility, Gelenbe and Muntz's completeness and our concept of pointwise independence, all boil down to essentially
the same thing. Although all three concepts are largely equivalent, the pointwise independence formulation enjoys the generality and convenience of being stated in purely probabilistic terms without any allusion to queueing-theoretic context or an underlying equilibrium assumption.

The utility of the pointwise independence concept is greatly enhanced by Corollary 5.2 and 5.4. The former provides a convenient computational test for pointwise independence which, in view of the latter, serves as a sufficient condition for mutually independent Poisson processes; its ease of application has been demonstrated in the examples of Sec. 7.

The utility of the weak pointwise independence concept derives from Theorem 5.1 and, in equilibrium situations, from Corollary 5.1. These may serve as necessity conditions for Poisson traffic processes by checking the actual behavior of \( \lim_{t \to a^+} \frac{3}{\delta_t} P_t(y,k) \) against the hypothesized one. This approach was demonstrated in Sec. 6; a more substantive application of this strategy can be found in [15] concerning traffic processes on the so-called nonexit arcs of a Jackson network.

The concept of pointwise independence (of traffic and state) has considerable relevance to the study of queueing network decomposition. A typical Markovian queueing network is postulated to have Poisson arrivals, independent servers and independent routing switches—the above being mutually independent processes. The problem of valid decompositions arises when one wishes to study one or more subnetworks in isolation via the theory available for the original network. In other words, under what conditions does a subnetwork satisfy all the
postulates of the original network? In the aforementioned typical queueing network it is required that all incoming streams into subnetwork nodes be mutually independent Poisson processes which, in addition, are also independent of the service and routing mechanisms operating within that subnetwork. Now, certain subnetworks may have a state process (an appropriately selected subvector of the original vector valued state process) which still retains the Markov property.

Consider the departure streams from such a subnetwork. As we have seen in the examples of Sec. 7, these departure streams and the compressed state are quite likely to be pointwise independent, in equilibrium. Consequently, if there is another subnetwork whose incoming customer streams are either exogenous or from other ones only, that subnetwork will indeed satisfy all the postulates of the original network, thus constituting an equilibrium original network in miniature. The reader is referred to [4] for an example of this situation from the domain of Jackson queueing networks.

Finally, we point out the plausibility of extending the results of this paper to traffic processes in Markov processes with time dependent transition rates or with continuous parameter and uncountably infinite state space. The latter could enable one to treat queues and queueing networks with more general arrivals and services, such as the limiting cases considered by Kelly [13] and Barbour [1].
