Non-Linear Transverse Electron Beam Dynamics in a Modified Betatron Accelerator

The transverse electron beam dynamics in a modified betatron accelerator is studied using a new approach. This approach is based on the two exact constants of the motion and the potentials at the center of the beam. The main advantage of the present technique is that the ring orbits can be accurately determined over the entire minor cross-section of the torus and not only near the minor axis. Our results indicate that the electron ring orbits, in the plane transverse to the toroidal magnetic field, always close inside the vacuum chamber and their topology is often substantially different than that predicted from the linear theory.

NON-LINEAR TRANSVERSE ELECTRON BEAM DYNAMICS
IN A MODIFIED BETATRON ACCELERATOR

I. Introduction

High energy accelerators capable of producing high current electron beams are rapidly becoming an active area of research. The motivation for developing these devices is related to potential applications of high current beams to the generation of high power coherent radiation\(^1\), x-ray radiography and national defense\(^2\).

Among the various accelerating schemes that have the potential to produce ultra-high power electron beams, induction accelerators\(^3\) appear to be the most promising. Induction accelerators are inherently low impedance devices and thus are ideally suited to drive high current beams. The acceleration process is based on the inductive electric field produced by a time varying magnetic field. The electric field can be either continuous or localized along the acceleration path.

Quite naturally, induction accelerators are divided into linear and cyclic. The linear devices are in turn divided into Astron-type\(^4\)\(^-\)\(^8\), Radlac-type\(^9\),\(^10\) and auto-accelerator\(^11\),\(^12\). In the first type, ferromagnetic induction cores are used to generate the accelerating field, while "air core" cavities are used in the second. In the auto-accelerator the air core cavities are excited by the beam's self fields rather than external fields. Similarly, cyclic devices can be divided into conventional\(^13\)\(^-\)\(^15\) and modified betatrons\(^16\)\(^-\)\(^20\). The field configuration in the modified betatron includes, in addition to the time varying betatron magnetic field, which is responsible for the acceleration, a strong toroidal magnetic field that substantially improves the stability of the accelerated beam.

The linear dynamics of high current electron rings in modified betatron fields, with and without stellarator fields, has been studied extensively.

Manuscript approved July 26, 1984.
during the last few years\textsuperscript{16-22}. These studies are based on the linearized equations of motion, i.e., they assume that the electron ring is confined near the minor axis of the torus.

In this paper we study the transverse ring dynamics in a modified betatron accelerator using a different approach. The ring orbits are not determined from the equations of motion but rather from the two exact constants of the motion and the potentials at the centroid of the ring. The main advantage of the present approach is that the ring orbits can be determined over the entire minor cross-section of the torus and not only near its minor axis. The topology of orbits near the wall of the toroidal vacuum chamber is of vital importance during injection, since optimization of the confining region requires the beam to be injected far away from the minor axis of the torus\textsuperscript{24,25}. It has been found that the shape of the ring orbits, in the transverse to the toroidal magnetic field plane, can be very complex, in particular in the high current limit.

II. Constants of the Motion

Consider an electron ring inside a perfectly conducting torus of circular cross section as shown in Fig. 1. The center of the ring is located at a distance $\Delta r, \Delta z$ from the minor axis of the torus. The kinetic energy $mc^2 \gamma$ of a reference electron that is located at the position $r,z$ varies according to the equation

$$mc^2 \frac{d\gamma}{dt}(r,z) = -|e| \hat{\gamma} \cdot \hat{E}(r,z),$$

(1)

where $\hat{E}(r,z)$ is the total electric field at the position of the reference electron. The electric field is related to the space charge $\varphi$ and magnetic
vector potential $\hat{A}$ by

$$\hat{E}(r,z) = -\nabla \phi - \frac{1}{c} \frac{\partial \hat{A}}{\partial t},$$

(2)

where the total time derivative of $\phi$ is given by

$$\frac{d\phi}{dt} = \frac{\partial \phi}{\partial t} + \nabla \cdot \nabla \phi.$$  

(3)

For the problem of interest, the accelerating fields vary slowly in time and thus

$$\frac{\partial \hat{A}}{\partial t} = \frac{\partial \phi}{\partial t} = 0.$$  

(4)

Combining Eqs. (1) to (4), we obtain

$$\frac{d\gamma(r,z)}{dt} - \frac{|e|}{mc^2} \frac{d\phi(r,z)}{dt} = 0$$

or

$$\gamma(r,z) - \frac{|e|}{mc^2} \phi(r,z) = \text{constant.}$$  

(5)

According to Eq. (5) the sum of the kinetic and potential energy of the reference electron is conserved.

Since the fields of the modified betatron configuration are independent of the toroidal angle $\theta$, the canonical angular momentum $P_\theta$ is also a constant of the motion, i.e.,

$$P_\theta = \gamma m r v_\theta - \frac{|e|}{c} r A_\theta = \text{constant},$$  

(6)
where $A_\theta$ is the toroidal component of the total magnetic vector potential and $v_\theta$ is the toroidal velocity of the reference electron.

Assuming that $v_\theta = v$ and eliminating $\gamma$ from Eqs. (5) and (6), it is obtained

$$\left[ \left( \frac{P_\theta}{mc^2} + \frac{|e|}{mc} A_\theta(r,z) \right)^2 + 1 \right]^{1/2} - \frac{|e|}{mc^2} \Phi(r,z) = \text{constant},$$

or, at the centroid of the ring

$$\left[ \left( \frac{P_\theta}{mcR} + \frac{|e|}{mc^2} A_\theta(R,Z) \right)^2 + 1 \right]^{1/2} - \frac{|e|}{mc^2} \Phi(R,Z) = \text{constant}.$$  

For very high energy beams, i.e., when $\gamma^2 >> 1$, Eq. (7b) is reduced to

$$\frac{P_\theta}{mcR} + \frac{|e|}{mc^2} [A_\theta(R,Z) - \Phi(R,Z)] = \text{constant}.$$  

This non-linear conservation law can furnish very useful information on the motion of the ring in the $r,z$ plane, provided that the potentials $A_\theta$ and $\Phi$ at the center of the ring are known. It should be noticed that Eqs. (7) are independent of the toroidal magnetic field.

III. The Potentials

In Eq. (7), the total magnetic vector potential $A_\theta(r,z)$ is

$$A_\theta(r,z) = A_\theta^{\text{ext}}(r,z) + A_\theta^{\text{self}}(r,z),$$

where $A_\theta^{\text{ext}}(r,z)$ is the external and $A_\theta^{\text{self}}(r,z)$ is the self magnetic vector potential.
It is assumed that the betatron magnetic field is described by

\[ A_\theta^{\text{ext}}(r,z) = B_{zo} \left[ \frac{r}{r^{2-n}} \right] \left( \frac{r}{2-n} \right) + \frac{r_0^2}{r} \left( 1-n \right) + \frac{nz^2}{2r} \], \quad (8) \]

where \( B_{zo} \) is the magnetic field at \( r=r_0, z=0 \) and \( n \) is the external field index, i.e.,

\[ n = -\frac{r_0}{B_{zo}} \frac{\partial B_z}{\partial r} \left( r, 0, 0 \right). \]

For a cylindrical electron beam inside a straight perfectly conducting cylindrical pipe of circular cross section, the self potentials can be computed exactly, even for large beam displacements from the minor axis of the torus. In the local coordinate system \( \rho, \phi \) the self potentials inside the beam, i.e., for \( |\rho-\Delta| < r_b \) are given by

\[ A^\text{self}_\theta(\rho,\phi) = -2|e| N_\| \beta_\theta \left[ \frac{1}{2} + \frac{\ln a}{r_b} - \frac{[\rho^2 + \Delta^2 - 2\rho \Delta \cos (\phi-\alpha)]}{2r_b^2} \right. \]

\[ - \sum_{l=1}^{\infty} \left( \frac{\Delta}{a} \right)^l \left( \frac{\Delta}{a} \right)^l \left[ -1 \cos (\phi-\alpha) \right], \quad (9a) \]

and

\[ \Phi(\rho,\phi) = -2|e| N_\| \frac{1}{2} + \frac{\ln a}{r_b} - \frac{[\rho^2 + \Delta^2 - 2\rho \Delta \cos (\phi-\alpha)]}{2r_b^2} \]

\[ - \sum_{l=1}^{\infty} \left( \frac{\Delta}{a} \right)^l \left( \frac{\Delta}{a} \right)^l \left[ -1 \cos (\phi-\alpha) \right], \quad (9b) \]
At the beam center, i.e., for \( \rho = \Delta \) and \( \phi = \alpha \), Eqs. (9a) and (9b) become

\[
A_{\theta}^{self}(R,Z) = -2 |e| N \frac{a}{r_b} \left[ \frac{1}{2} + \ln \frac{a}{r_b} + \ln \left[ 1 - \frac{(R-r_0)^2 + Z^2}{a^2} \right] \right], \tag{10a}
\]

and

\[
\phi(R,Z) = -2 |e| N \frac{a}{r_b} \left[ \frac{1}{2} + \ln \frac{a}{r_b} + \ln \left[ 1 - \frac{(R-r_0)^2 + Z^2}{a^2} \right] \right], \tag{10b}
\]

where \( N \) is the linear electron density, \( r_b \) is the minor radius of the beam, \( a \) is the minor radius of the conducting pipe and \( \beta_{\theta} = \frac{v_{\theta}}{c} \).

Figure 2 shows the ratio \( -A_{\theta}^{self}/2N \) from Eq. (10a) at \( Z = 0 \), together with results from the computer code PANDIRA. This code solves the differential equations for \( \lambda \) and \( \phi \) in a non-uniform triangular mesh in \( r-z \) coordinates and its present version has been developed by R.F. Holsinger. The various parameters for the runs shown in Figs. 2 to 5 are listed in Table 1. The agreement between Eq. (10a) and the numerical results is excellent. The maximum difference between the analytical and numerical results is less than 0.4%.

Figure 3 shows the stream function \( \psi = RA_{\theta}^{self} \). In contrast to \( A_{\theta}^{self} \), the stream function \( \psi \) peaks away from the minor axis of the torus. The radial displacement of the peak can be computed from \( \delta \psi/\delta R = 0 \) and is given by the relation

\[
\Delta_\rho = (a/2) \left( \frac{a}{r_0} \right) \left( \frac{1}{2} + \ln \frac{a}{r_b} \right).
\]

This relation predicts that \( \psi \) peaks 2.8 cm from the minor axis, which is not far-off from the 2.6 cm of Fig. 3.

Results for the electrostatic potential are given in Fig. 4. Again the agreement between Eq. (10b) and numerical results is excellent. The maximum
difference $\Delta \phi$ between the electrostatic potential computed from PANDIRA and that of Eq. (10b) is less than 2%.

Figure 5 shows the stream function $\psi$ for a torus with a major radius $r_o = 32$ cm. In agreement with the approximate expression for $\Delta \phi$, the displacement of the peak increased by about a factor of 3.

To obtain a better understanding of the potentials inside a perfectly conducting torus, we solved the differential equations for $\phi$ and $\tilde{\phi}$ to first order in the ratio $a/R$, but to any order in the normalized displacement $\Delta/a$.

For a constant particle density $n_o$ ring and to second order in $\Delta/a$, the electrostatic potential and the stream function $\psi$ at the center of the ring are given by

$$
\phi(R,Z) = -2 Nz |e| \left[ \frac{1}{2} + \ln \left( \frac{a}{r_b} \right) \right] \left[ \frac{(R-r_o)^2 + z^2}{a^2} \right] - \frac{r_b}{8a^2} \left[ \frac{R-r_o}{R} \right], \quad (11a)
$$

$$
\psi(R,Z) = -2 N_z |e| R \beta_\theta \left[ \frac{1}{2} + \ln \left( \frac{a}{r_b} \right) \right] \left[ \frac{(R-r_o)^2 + z^2}{a^2} \right] - \frac{3r_b}{8a^2} \left[ \frac{R-r_o}{R} \right], \quad \text{for } \delta = \text{constant} \quad (11b)
$$

and

$$
\psi(R,Z) = -2N_z |e| R \beta_\theta \left[ \frac{1}{2} + \ln \left( \frac{a}{r_b} \right) \right] \left[ \frac{(R-r_o)^2 + z^2}{a^2} \right] - \frac{r_b}{8a^2} \left[ \frac{(R-r_o)}{R} \right],
$$

for $J_\theta = \text{constant.} \quad (11c)$
Similarly, the fields at the centroid of the ring are given by

\begin{equation}
E_r = \frac{-2e|N_s|}{a} \left[ (\frac{R-r_o}{a}) + \frac{ln}{\frac{a}{r_b}} + \frac{r_b^2}{8Ra} \right], \quad (12a)
\end{equation}

\begin{equation}
E_z = \frac{-2e|N_s|}{a} \left( \frac{Z}{a} \right), \quad (12b)
\end{equation}

\begin{equation}
B_r = \frac{-2e|N_s|\beta_\theta}{a} \left( \frac{Z}{a} \right), \quad (12c)
\end{equation}

\begin{equation}
B_z = \frac{-2e|N_s|\beta_\theta}{a} \left[ (\frac{R-r_o}{a}) - \frac{a}{2R} \left( ln \frac{a}{r_b} + 2 \right) \right] + \frac{r_b^2}{8Ra}], \quad \text{for } \beta = \text{constant}, \quad (12d)
\end{equation}

and

\begin{equation}
B_z = \frac{-2e|N_s|\beta_\theta}{a} \left[ (\frac{R-r_o}{a}) - \frac{a}{2R} \left( ln \frac{a}{r_b} + 1 \right) \right] + \frac{r_b^2}{8Ra}], \quad \text{for } J_\theta = \text{constant}. \quad (12e)
\end{equation}

The toroidal term in Eq. (11) is very small for the parameters of interest and therefore it is not surprising that the potential at the center of the ring are approximately cylindrical.

For low energy rings the small toroidal term could be important and could have a profound effect on the shape of the orbits. However, when \( \gamma \gg 1 \), the potentials for \( n_o = \text{constant} \) and \( J_\theta = \text{constant} \) become approximately equal and hence they do not contribute substantially in Eq. (7c).
IV. Transverse Ring Orbits

Equation (7b) has been solved numerically, using the potentials of Eq. (11). Typical macroscopic beam orbits in the r,z plane are shown in Figs. 6 to 8. The various parameters for those runs are listed in Table II. Only orbits that are at least one beam minor radius away from the wall are shown. Each orbit corresponds to a different value of the constant in Eq. (7b). A striking feature of the results is the sensitivity of the orbits to the value of the constant in Eqs. (7).

The number marked in every fourth orbit is equal to $10^4 [\text{constant} - <\text{constant}>]$, where the average value of the constant, i.e. $<\text{constant}>$ for each run is shown at the top of the figure. For all the cases tested, less than 3\% change in the constant of the motion was sufficient to generate orbits that extend over the entire minor cross-section of the torus. Orbits shown with solid lines correspond to a constant that is greater than $<\text{constant}>$ and those shown with a dashed line correspond to a constant that is less than $<\text{constant}>$.

All the orbits close inside the vacuum chamber. However, a fraction of them lie inside the annular region that extends from the dotted-dashed line to the wall. This region has a width that is less than the beam radius and hence part of the beam will strike the wall.

Ring orbits in the r,z plane from Eq. (7b) using the potentials of Eq. (10), i.e., emitting the toroidal terms, are shown in Figs. 9 to 11. It is apparent that there is not any noticeable difference between these orbits and those of Figs. 6 to 8.
The predictions of Eq. (7b) are in very good agreement with the results from our particle in cell (PIC) computer simulation.\textsuperscript{20} Figures 12 to 14 show three computer simulation runs. As may be seen from Table III, with the exception of the betatron field, the various parameters in the simulation are the same with those of Figs. 6 to 8. The slightly lower value of the betatron field in Figs. 12 to 14 is related to the different radial profiles for $J_\theta$ in the simulation and the potentials of Eq. (11). The orbit wiggles are due to the finite ring emittance, which was taken zero in the derivation of Eq. (7b). It should be noticed that in these computer simulation runs the electron ring was reasonably well matched to the magnetic field as it is manifested from the small variations in the axial and radial ring envelopes shown in Fig. 15.

In the general case, it is difficult to derive an explicit expression for the ring orbits in the transverse plane from Eqs. (7b) and (11). However, in the limit $\gamma^2 >> 1$, $\beta_\theta/\beta = 1$ and $\nu/\gamma << 1$, such an expression can be obtained near the minor axis of the torus.

Since $\beta_\theta = \beta$ and $\gamma \beta = \gamma - 1/2 \gamma$, Eqs. (5) and (6) give

$$\frac{P_\theta}{mc R} + \frac{|e|}{mc^2} A_\theta^{\text{ext}} + \frac{|e|}{mc^2} (A_\theta^{\text{self}} - \phi) + \frac{1}{2 \gamma} = \text{constant} = G. \quad (13)$$

Expanding $\gamma$ near $r_0$ and using Eq. (5), it is obtained

$$\delta \gamma = \gamma - \gamma_0 = \frac{|e|}{mc^2} \left. \frac{3 \phi}{3r} \right|_{r_0} |\Delta r| + \frac{3G}{3r} \left| \frac{\Delta r}{r_0} \right|,$$

where $\Delta r = R - r_0$. It is shown in the next section that $\frac{3G}{3r} \left| \frac{\Delta r}{r_0} \right| = 0$ and thus the above equation becomes

$$\delta \gamma = \gamma - \gamma_0 = \frac{|e|}{mc^2} \left. \frac{3 \phi}{3r} \right|_{r_0} |\Delta r|. \quad (14)$$
From Eqs. (11a) and (11c), the difference in the self potentials can be written as

\[ A_{\text{self}}^\theta - \phi = 2N \zeta |e| \left\{ 1/2 + \ln \frac{a}{r_b} - \frac{\Delta r^2 + \Delta z^2}{a^2} - \frac{r_b^2}{8a^2} \frac{\Delta r}{R} \right\} (1-\beta_\theta). \] (15)

\[ 1-\beta_\theta = 1-\beta = 1/2\gamma^2 \] and substituting \( \delta \gamma \) from Eq. (14) in the expansion for \( 1/\gamma^2 \), it is obtained

\[ 1-\beta_\theta = \frac{1}{2\gamma_o^2} \left[ 1 - \frac{2}{\gamma_o} \frac{|e|}{mc^2} \frac{\delta \phi}{\delta r} |r_o \Delta r \right]. \] (16)

Similarly, expanding \( 1/2\gamma \) as

\[ \frac{1}{2\gamma} = \frac{1}{2\gamma_o} - \frac{1}{2\gamma_o mc^2} \frac{\delta \phi}{\delta r} |r_o \Delta r , \] (17)

and \( 1/R \) as

\[ \frac{1}{R} = \left( \frac{1}{r_o} \right) \left[ 1 - \frac{\Delta r}{r_o} + \left( \frac{\Delta r}{r_o} \right)^2 \right], \] (18)

and using a linear expression for the external vector potential

\[ A_{\text{ext}}^\theta = B z_o r_o \left[ 1 + \frac{\Delta r^2 (1-n)}{2r_o^2} + \frac{\Delta z^2 n}{2r_o^2} \right], \] (19)
Eqs. (13) to (19) give

\[
\frac{p_\theta}{mcr_o} + \frac{\omega_{ext}}{2c} \left[ \frac{r_o}{z_o} (1-n) - \frac{v r_o}{2 c} \right] \left( \frac{\Delta r}{r_o} \right)^2 + \left[ \frac{z_o}{2 c} - \frac{v r_o}{2 c} \right] \left( \frac{\Delta z}{r_o} \right)^2
\]

\[
- \left[ \frac{p_\theta}{mcr_o} + \frac{\nu}{2} \left( \frac{r_b}{2a} + \ln \frac{a}{r_b} \right) \right] \left( \frac{\Delta r}{r_o} \right) = \tilde{G},
\]

where

\[
\Delta r = R - r_o, \Delta z = Z, \tilde{G} = G - \left[ \frac{1}{2} \gamma_o^2 + \frac{p_\theta}{mcr_o} \right]
\]

\[
+ \left( \nu \gamma_o^2 \right) \left[ \frac{1}{2} + \ln \frac{a}{r_b} \right] + \omega_{ext} \left( \frac{r_o}{c} \right), \quad \omega_{ext} = e|E_{zo}/mc,
\]

and \(\nu\) is the Budker's parameter.

Equation (20) describes the ring orbits near the minor axis, when \(\gamma^2 \gg 1\). These orbits are centered around the minor axis of the torus when the coefficient of the \(\left(\frac{\Delta r}{r_o}\right)\) term is zero, i.e., when

\[
\frac{p_\theta}{mcr_o} = - \frac{\nu}{2 \gamma_o} \left[ \frac{r_b}{2a} + \ln \frac{a}{r_b} \right]
\]

For \((r_b/a)^2 \ll 1\) and \(\gamma_o \gg 1\), Eq. (21) predicts that \(\frac{p_\theta}{mcr_o} = 0\). Therefore, the orbits are circular when the external field index is approximately equal to 0.5, in agreement with the computer results shown in Figs. 7 and 13.

This result is not in agreement with previous work,\(^{19,20,22}\), which for \(J_\theta = \) constant predicts circular orbits when

\[
n = \frac{1}{2} \frac{\left[ 1 - \left( \nu \gamma_o \right) \ln \left( \frac{a}{r_b} \right) \right]}{1 + \left( 2 \nu \gamma_o \right) \left[ \frac{1}{2} + \ln \frac{a}{r_b} \right]}
\]
It has been determined that the discrepancy is due to an inconsistency in the expansion that gave erroneous results for the two slow frequencies $\omega_r$ and $\omega_z$ and made the expression for the field index, i.e., Eq. (22), invalid.

Additional results from Eq. (7b) are shown in Figs. (16) to (19). The various parameters for these runs are listed in Table IV. As the ring current increases, the orbits are dramatically modified as manifested by the results of Fig. 18. Midway to the wall, the orbits change from circles to finite width C shaped forms that evolve to crescents or "bananas". At the tips of the crescents the bounce frequency becomes zero and the macroscopic beam motion transitions from diamagnetic to paramagnetic and vice versa. Particle in cell computer simulation results show that the beam can go through such a transition without any noticeable interruption. A typical case is shown in Fig. 20. The various parameters of this run, that lasted for more than 1 microsecond, are listed in Table V. Figure 20a shows the orbit of the center of the ring in the r,z plane. The time interval between two successive dots is 20 nsec. According to Figs. 20b and 20c the ring envelope changes only slightly during the run.

V. Extreme of the Constant of the Motion

The extreme of Eq. (5) furnishes useful information on the dynamics of the ring in the r-z plane. First, we will show that this extreme is the radial balance equation of motion for the reference electron.

Setting the partial derivative of Eq. (5) with respect to r equal to zero

$$\frac{3\gamma}{3r} - \frac{|e|}{mc^2} \frac{3\theta}{3r} = 0,$$

(23)
and using the relation $\gamma = (1 + \beta^2 \gamma^2)^{1/2}$ and Eq. (6), we obtain

$$\frac{3\gamma}{3r} = \beta \left[ -\frac{P_\theta}{mcr^2} + \frac{|e|}{mc^2} \frac{3A^\text{ext}}{3r} + \frac{|e|}{mc^2} \frac{3A^\text{self}}{3r} \right], \quad (24)$$

where we have assumed that $\beta = v/c$ is approximately equal to $\beta_\theta = v_\theta/c$.

Substituting Eq. (6) into Eq. (24) and using the equations

$$B_{z}^\text{ext} = \frac{A_\theta^\text{ext}}{r} + \frac{3A^\text{ext}}{3r}, \quad (25a)$$

$$B_{z}^\text{self} = \frac{A_\theta^\text{self}}{r} + \frac{3A^\text{self}}{3r}, \quad (25b)$$

and

$$E_r = -\frac{3A_\theta}{3r}, \quad (25c)$$

it is obtained

$$-\gamma m \frac{v_\theta^2}{c} = -|e| \left[ E_r + \frac{v_\theta}{c} (B_{z}^\text{ext} + B_{z}^\text{self}) \right], \quad (26)$$

i.e., the radial balance equation. This equation gives the equilibrium position of the ring, which is located along the $\hat{e}_r$ axis. At this position the reference electron at the centroid of the ring moves only along the toroidal direction, i.e., $v_r = v_z = 0$.

When the equilibrium position is at $r = r_o$, the toroidal velocity of the reference electron can be determined from Eqs. (6) and (21) and is
With the exception of the very small term on the numerator, Eq. (27) is the same with the expression reported previously (20) for beams with square current density profile.

The external magnetic field $B_{z0}^{\text{ext}}$ required to confine the ring at $r = r_0$ can be readily found from Eq. (27). Omitting the small term in the numerator of Eq. (27), we obtain

$$v_{\theta 0} = \frac{\frac{r_0}{2} \left[ \frac{r_b}{2a} \right]^2}{\left[ 1 + \frac{2\nu}{\gamma_0} \left( \frac{1}{2} + \ln \frac{a}{r_b} \right) \right]}.$$  \hspace{1cm} (27)

$$B_{z0}^{\text{ext}} = B_{z0}^{\text{sp}} \left[ 1 + \frac{2\nu}{\gamma_0} \left( \frac{1}{2} + \ln \frac{a}{r_b} \right) \right],$$  \hspace{1cm} (28)

where the single particle magnetic field is $B_{z0}^{\text{sp}} = \frac{\gamma_0 B_0}{r_0} \frac{mc^2}{|e|}.$

The magnetic field required to maintain the beam at an equilibrium position that is different than $r_0$ can also be determined from the radial balance equation. Substituting $E_r$ and $B_{z\text{self}}$ from Eqs. (12a) and (12e) into Eq. (26), it is obtained

$$B_{z}^{\text{ext}} = B_{z}^{\text{sp}} \left[ 1 + \frac{2\nu}{\gamma} \left[ \frac{1}{2} + \ln \frac{a}{r_b} + \frac{R(R-r_0)}{a(\gamma\beta)} + \frac{r_b^2}{8a(\gamma\beta)} \right] \right].$$  \hspace{1cm} (29)

Equation (29) has been derived under the assumption that $\nu$ is not a function of $R$.

The predictions of Eq. (29) are in excellent agreement with the result of the NRL computer simulation code. Three examples are shown in Table VI.
VI. Summary

The non-linear beam dynamics in the plane transverse to the toroidal magnetic field is studied using the two constants of the motion, instead of the linearized equations of motion. This approach allows the beam orbits to be determined over the entire minor cross-section of the torus and not only near the minor axis.

It was found that the orbits are sensitive to the external field index, to the value of the constant of Eqs. (7) and to the beam current. The orbits in the r,z plane always close inside the vacuum chamber, although often very near the perfectly conducting wall. As a result, beam interruption will occur whenever the electron ring moves along one of these orbits.

In addition, it has been shown that the extreme of Eq. (5) provides information on the external magnetic field required to confine the ring at its equilibrium position and the displacement of the equilibrium position when the beam energy is not matched to the vertical field.
