BASED UPON LEAD TELLURIDE

Abstract

Lead telluride type semiconductors are used in the fabrication of thermoelectric modules currently employed in a number of US military applications. This report covers the programme of research undertaken in the Department of Physics, Electronics and Electrical Engineering at UWIST Cardiff to produce materials based upon lead telluride with improved "figures of merit" and hence greater thermoelectric conversion efficiency.

One way of improving the figure of merit is by reducing the lattice thermal conductivity of the material. This can be achieved by increasing phonon-grain boundary scattering. A realistic theoretical model has been developed for lead telluride and used to investigate the lattice thermal conductivity as a function of grain size and level of doping. In optimally doped material ($10^{24}$-10$^{28}$m$^{-3}$) with a grain size of 1µm, the reduction in lattice thermal conductivity was predicted to be 4-6 percent compared with equivalent single crystal. Thermal diffusivity measurements on small grained compacts supported this prediction.

Phonon grain boundary scattering is enhanced in semiconductor alloys because of the presence of disorder scattering and the theoretical model was extended to take this factor into account. PbSnTe and PbGeTe were identified as alloys whose lattice thermal conductivity could be significantly decreased by a reduction in grain size and in optimally doped compacted material with a grain size of 0.5µm the reduction compared to equivalent single crystal material was estimated to be 11 and 14 percent respectively.

It is concluded that provided the electrical properties of compacted lead telluride material can be maintained close to that of single crystal; the thermoelectric figure of merit can be substantially improved by employing a fine grain size. In PbGeTe with a grain size of 1µm, the improvement in the thermoelectric figure of merit is estimated to be about 10 percent.

II GENERAL INTRODUCTION

Multifuel thermoelectric generators employing modules based upon lead telluride technology are used in a number of military applications\(^1\). In addition to their multifuel capability these generators are difficult to detect by visual, aural, or thermal infrared.\(^2\) Clearly any improvement in the thermoelectric conversion efficiency of the generator would result in a saving in fuel - an important consideration when the device is used in a tactical situation.

The factors which determine the conversion efficiency (\(\eta\)) of a thermoelectric generator have been exhaustively dealt with in the literature.\(^3\) It is suffice to state that once the operating temperature and the temperature difference over which the generator operates has been decided, \(\eta\) depends solely upon the so called figure of merit \(Z\) of the thermocouple material, where \(Z = \frac{a^2 \sigma}{\lambda}\), \(a\) is the Seebeck coefficient, \(\sigma\) the electrical conductivity. The thermal conductivity \(\lambda\) is the sum of \(\lambda_L\), a contribution due to the lattice and \(\lambda_e\) an electron (or hole) contribution.

The parameters which occur in the expression for the figure of merit are functions of the carrier concentration (usually expressed in terms of the reduced Fermi energy \(\xi\)) and in the established high temperature thermoelectric material silicon-germanium alloy, \(Z\) is optimized at around \(10^{25}-10^{26} m^{-3}\).\(^2\) However, at these high carrier concentrations \(\lambda_L\) still accounts for about 75 percent of \(\lambda\) and it is anticipated that \(\lambda_L\) will contribute a similar proportion to the thermal conductivity of lead telluride. Consequently a reduction in \(\lambda_L\) would result in a corresponding increase in the figure of merit of lead telluride and hence in the materials thermoelectric conversion efficiency.

It has been reported that phonon-grain boundary scattering has a significant effect on reducing the lattice thermal conductivity of silicon germanium alloys.\(^13\) This phenomenon does not appear to be accompanied by a deterioration in the other parameters which occur in the figure of merit although the long term behaviour of small grain size material when subjected to high temperatures has not been reported. Consequently small grain size silicon germanium alloys exhibit a higher figure of merit than comparable "single crystal" or large grain size material. Grain boundary scattering is particularly favoured in silicon-germanium alloy because the large difference in atomic masses of the constituent atoms give rise to substantial alloy disorder scattering. However, this
phenomenon will also be present in other thermoelectric alloys and in alloy compounds such as those based upon lead telluride.

The United States Army is currently evaluating the performance of a number of improved thermoelectric materials for possible use in future thermoelectric generators. Evidently information on the reduction in thermal conductivity and hence potential improvement in thermoelectric performance, which accompanies the use of small grain size lead telluride type material and on the conditions which optimise the thermoelectric figure of merit of these materials is relevant to their programme of material evaluation.

III OBJECTIVES

The objectives of the programme of research described in this report were:-

1(a) Initially to develop a semiquantitative theoretical model of lead telluride. Use the model to estimate the relative reduction in the lattice thermal conductivity compared to single crystal material with decrease in grain size and hence improvement in the thermoelectric figure of merit.

(b) Substantiate the theoretical prediction by preparing <5μm grain size compacts of lead telluride and measuring the relevant transport properties.

2 Depending upon the success or otherwise in achieving these initial objectives the second phase of the work was to:-

(a) Develop a realistic theoretical model for the absolute magnitude of the thermal conductivity of lead telluride. Use the model to identify alloys based on lead telluride whose lattice thermal conductivity offer the best potential for reduction as a result of phonon-grain boundary scattering. Determine the conditions for optimising the thermoelectric figure of merit of these alloys.

(b) Attempt to comminate very small grain size (<0.5μm) lead telluride material.

For convenience in presentation the work reported is divided into two stages 1. Theoretical and 2. Experimental

IV DEVELOPMENT OF A THEORETICAL MODEL FOR LEAD TELLURIDE

1. Introduction

The initial objective to estimate the relative reduction in lattice thermal conductivity, compared to single crystal, with decrease in grain size was fairly straightforward. A two band model with parabolic multivallied energy band structure was considered. Acoustic phonon
scattering was taken to be the dominant scattering mechanism, intervalley scattering is neglected and no distinction made between the conductivity effective mass and the density-of-states effective mass. Although the model was later improved, preliminary calculations indicated that the relative changes in thermal conductivity due to phonon-grain boundary scattering, and consequent relative changes in the thermoelectric figure of merit are fairly insensitive to the inclusion of these refinements.

However, the development of a realistic model for lead telluride for use in identifying potentially good alloys based on lead telluride presented considerable difficulties. The theoretical model must give good agreement with experimental data cited in the literature and this involved obtaining the separate electronic ($\lambda_e$) and lattice ($\lambda_L$) contributions to the thermal conductivity. A prerequisite for this analysis is a knowledge of the Lorenz number. A literature survey revealed that there is very little European or United States published information on the value and behaviour of the Lorenz number for lead telluride. The realistic model developed considers both acoustic and optical phonon scattering. It takes into account the non parabolic nature and multivalleyed structure of the energy bands, including intervalley scattering. Minority carrier effects will also be significant over part of the temperature range of operation of the materials and should be included. The principal elements of the theoretical model are discussed in the following section.

2. Lattice thermal conductivity

At temperatures above room temperature, a simple formulation for the lattice thermal conductivity can be used which includes the various phonon scattering mechanisms. The lattice thermal conductivity is expressed in terms of three parameters $A$, $B$ and $C$ which relate to phonon scattering by alloy disorder, free carriers and grain boundaries respectively. Defining $\lambda_o$ as the thermal conductivity of a large, perfect (notional) crystal, the lattice thermal conductivity is given by:

$$\frac{\lambda_L}{\lambda_o} = \left[1 + \frac{5k_o}{9}\right]^{-1} \left[ L_t(A,B,C) + \frac{k_o}{1 + k_o} L_e(A,B,C) \right]$$
where \( L_n(A,B,C) = \frac{\int_0^1 x^n dx}{Ax^4 + x^2 + Bx + C} \)

Here \( x = \frac{\hbar \omega}{k_B T} \) and \( k_0 = \frac{\tau_u}{\tau_N} \) is the ratio of the phonon relaxation times for Umklapp and Normal processes. \( k_B \) is Boltzmann's constant and \( T \) is the temperature. There is no advantage in this present study to undertake detailed calculations of the contributions to the thermal conductivity from separate polarizations and an average acoustic branch is assumed. The various phonon relaxation times are as described in the literature; the phonon-electron scattering relaxation time is given by

\[
\tau_{pe}^{-1} = B' x
\]

\( A, B \) and \( C \) are given by

\[
A = \frac{\frac{\pi \Omega_0^2 \omega_D^2}{2V^2 k_B [1 + \frac{5k_0}{9}]}}{\text{Alloy disorder scattering}}
\]

\[
B = \frac{\frac{2\pi^2 \lambda_0 k_B}{k_B \omega_D^3 (1 + \frac{5k_0}{9})}}{\text{Free carrier scattering}}
\]

\[
C = \frac{\frac{2\pi^2 \lambda_0 \tau_{pe}}{V^2}}{\text{Grain boundary scattering}}
\]

The various parameters have the same meaning as in the literature. It is usual to express \( C \) in terms of a parameter \( D \), which is inversely proportional to the grain size \( L \) and they are related...
by $D=CT$ where $T$ is the temperature. $A=0$ corresponds to unalloyed material with no disorder present, $B=0$ corresponds to undoped material and $C=0$ to single crystal material. In general $\lambda(A,B,C=0) = \lambda_{\text{single}}$ represents the lattice thermal conductivity of a doped single crystal alloy while $\lambda(A,B,C) = \lambda_{\text{sintered}}$ represents the lattice thermal conductivity of a compacted (sintered) alloy.

3. **Electronic contribution to the thermal conductivity**

(i) **Introduction**

Lead telluride and its alloys possess a narrow energy band gap ($E_g$). These materials have small electron effective masses and the density of states which varies as $m^*_{1/2}$ is also relatively small. Consequently a relatively small number of carriers will be sufficient to fill the bands up to high energy levels. The effective mass of electrons near the top of the conduction band become energy dependent\(^*\). In the model adopted a two band conduction band is considered with the following main features; the band extrema for the conduction and valence bands are assumed to be located at the same $k$ value. The energy separation from the other bands at this $k$ value is greater than the main energy gap and the momentum operator has non-zero matrix elements between the states corresponding to the extremal points. Non-parabolicity and the effective mass of both bands are defined by the interaction of the electron and hole bands only.

The energy dispersion law is of the form:-

$$\frac{\hbar^2 k^2}{2m^*_O} + \frac{\hbar^2 k^2}{2m^*_O} = E \left( 1 + \frac{E}{E_g} \right)$$

$k_\perp$ and $k_\parallel$ are the transverse and longitudinal components of the wave vector and $m^*_O$ and $m^*_O$ are the components of the effective mass tensor near the band extremum. This is usually referred to as the "Kane model". The energy dependence of the effective mass is given by :-

$$m^* = m^*_O \left( 1 + \frac{2E}{E_g} \right)$$
For a multivallied structure with $N_v$ equivalent valleys the density of states effective mass is:

$$m_d^* = N_v^{2/3} \left( m_{\parallel}^* m_{\perp}^* \right)^{1/3} = N_v^{2/3} m_d^*$$

and the conductivity effective mass:

$$m_C^{*\ast} = \frac{1}{3} \left( m_{\parallel}^{*\ast} + 2m_{\perp}^{*\ast} \right)$$

The energy dependence of the effective mass manifests itself in the various transport coefficients; these are expressed in terms of averaged quantities such as $<\tau>$, $<\tau^2>$, $<\tau(E)>$ etc. In the case of non-parabolic energy bands:

$$<\tau_{Em}> = \int_0^\infty \frac{(-\delta f/\delta E)(\tau(E)/m^*(E))^{nEm}}{\int_0^\infty (-\delta f/\delta E)(k^2/m^*_C)^n) dE}$$

where $k = (2m_d^*)^{1/2} \left( E(1+E/E_g) \right)^{1/2}$

In lead telluride at room temperature, the contribution of impurity scattering to the carrier mobility is very small and will be negligible at the temperatures of operation of a thermoelectric device. Consequently only electron-phonon scattering mechanisms need to be considered.

3 (ii) Carrier scattering by acoustic phonons

The carrier relaxation time can be written as:

$$\tau \sim \frac{1}{IM^2 \rho(\eta)}$$

where $\eta = E/k_BT$ is the reduced carrier energy, $M$ is the matrix element for the electron-phonon interaction and $\rho(\eta)$ is the density of states. The calculation is simplified if it is assumed that the matrix element depends upon energy as for the case of a parabolic band. For scattering by acoustic phonons, this amounts to $IM^2 = constant$. The relaxation time is then given by:

$$\tau_{ac} \sim \frac{1}{\rho(\eta)} \frac{1}{\alpha} \frac{1}{[\eta(1+\beta_g \eta)]^{1/2}(1+2\beta_g \eta)}$$

where $\beta_g = k_BT/E_g$
The appropriate expression for \( \tau(\eta) \) which includes the energy dependence of \( M \) is given by\(^1\):

\[
\tau(\eta)^{-1} = \frac{n k_B T (\rho/N_V)}{\hbar C_1} \varepsilon^2 \left[ 1 - \frac{8 \beta g \eta (1 + 2 \beta g \eta)}{3(1 + 2 \beta g \eta)^2} \right]
\]

where \( C_1 \) is the elastic constant related to the average sound velocity, \( (\rho/N_V) \) is the density of state in a given valley and \( \varepsilon \) is the deformation potential constant.

The Lorenz factor is given by:

\[
x = \left[ \frac{1}{L^2} \right] - s^2
\]

where \( s = L^2/\rho L^2 \), and \( n_{M} \) are generalised.

Fermi integrals and defined as:

\[
n_{M}(s) = \int_{0}^{\infty} \left[ - \frac{\delta f}{\delta n} \eta^n (\eta (1 + 2 \beta g \eta))^M (1 + 2 \beta g \eta)^2 d \eta
\]

The reduced electrical conductivity is given by:

\[
\sigma = n k_N^0 \frac{\rho L^2}{(m^*_C)^L}
\]

With the carrier concentration \( n \) related to the reduced Fermi energy \( \xi \), by the expression:

\[
n = \frac{(2 m_0^* k_B T)^{1/2}}{3 n^2 h^3} \xi^{1/2}
\]

The carrier mobility \( \mu_{ac} \) due to acoustic phonon scattering is given by:

\[
\mu_{ac} = \frac{\text{constant}}{m_0^* m_0^* T^3/2} \frac{O_{L^2}}{O_{L^2}}
\]

3.(iii) Carrier scattering by polar optical phonons

The carrier relaxation time for scattering by polar optical phonons is given by\(^2\):
The Lorentz factor is given by:

\[ \tau_{\text{op}}^{-1} = \frac{2^{1/2} e^2 k_B T \hbar d^* \hbar}{(\chi_m^2 \chi_m^* \chi_m^0 \chi_m^0)^{1/2}} \left( \epsilon_m^{-1} - \epsilon_0^{-1} \right) \frac{1 + 2 \beta g \eta}{(1 + \beta g \eta)^{1/2}} \]

\[ x \left[ 1 - 5 \omega_m n(1 + 5 \omega_m^{-1}) - \frac{2 \beta g \eta (1 + \beta g \eta)}{(1 + 2 \beta g \eta)^2 (1 + 2 \beta g \eta)} \right] \]

where \( x = (\epsilon_0^2 L_z^2 / \epsilon_0^0 L_z^2) - \delta^2 \)

In the calculations, screening effects have not been taken into account. Polar optical scattering although appreciable in lead telluride materials, is not the dominant scattering mechanism. Consequently neglecting screening effects will not substantially affect the overall electronic transport properties.

The reduced electrical conductivity can be expressed as:

\[ \sigma' = N_0 k T^2 f(\theta_0 / T) m^*_d \sigma_0 \epsilon_0 / (\lambda \omega_0) \]

with \( K' = \frac{4 k_B^2}{3 e^2 n^2 \hbar (\epsilon_0^{-1} - \epsilon_m^{-1})} \)

where \( \epsilon_0 \) and \( \epsilon_m \) are the static dielectric constant and the dielectric constant at high frequencies respectively. \( \theta_0 \) is the temperature which corresponds to the optical phonon frequency at the zone boundary.

The carrier mobility \( \mu_{\text{op}} \) due to optical phonon scattering is given by:

\[ \mu_{\text{op}} = \frac{K'' f(\theta_0 / T)^2 L_z \hbar}{T^{1/2} m^*_d m^*_c \epsilon_0 \epsilon_0^{3/2}} \]

where \( K'' = \frac{8 \hbar^2 (2 n k_B)}{3 \epsilon (2 n k_B)^{3/2} (\epsilon_0^{-1} - \epsilon_0^{-1})} \)
3 (iv) Multivalley energy band structure and intervalley scattering

A multivalley energy band structure together with intervalley scattering must be included in the theoretical model for lead telluride type materials if quantitative correspondence is sought between theory and experimental data. Although the inclusion of a multivalley structure and non-parabolicity of the energy momentum relationship makes the computation lengthy, the model is tractable in the details. The greatest difficulty is in accurately calculating the effect of intervalley scattering. In this analysis a method due to Herring\textsuperscript{21} is followed. The transition of an electron from one valley to another (in k space) is accompanied by a large change in momentum. The phonons which participate in this scattering process lie near the edge of the Brillouin zone. At the Brillouin zone boundary, the acoustic and optical branches are either degenerate or close to one another. The frequency of the intervalley mode $\omega_i$ has a value between the frequency of the two modes at the zone boundary, with the relaxation time for intervalley scattering of carriers given by:

$$\tau_i^{-1} = \frac{W_i \left[ \left( \frac{E}{k_B \theta_i} \right) + 1 \right]^{1/2} + \exp(\theta_i/T) \Re \left[ C(\frac{E}{k_B \theta_i}) - 1 \right]}{\exp(\theta_i/T) - 1}$$

where $W_i$ is a rate constant. Averaging $\tau_i$ over a Maxwell-Boltzmann distribution function gives for thermal carriers.

$$\langle \tau_i^{-1} \rangle = W_i \left( \frac{2Z}{\pi} \right) \frac{K_1(Z)}{Z} \sinh(Z)$$

where $K_1$ is a modified Bessel function of the second kind and $Z = \theta_i/2T$.

The total relaxation time of carriers is obtained by adding the inverse relaxation times for the acoustic scattering $\tau_{ac}$ and intervalley scattering $\tau_i$. The ratio $\mu/\mu_0$, where $\mu$ is the mobility can be calculated\textsuperscript{21} as a function of $T/\theta_i$ and the mobility obtained for various values of $W_i/W_i$: here $\mu_0 = \mu_{ac}(T/\theta_i)^{3/2}$, $\theta_i = \hbar \omega_i/k_B$ and $W_i$ is the rate constant for intervalley scattering.

The use of Maxwell-Boltzmann statistics may well be inappropriate at the high carrier concentrations present in thermoelectric semiconductors. However, lead telluride exhibits intervalley scattering to a relatively small degree. Consequently, any shortcomings of the theoretical model which may result from the use of Maxwell-Boltzmann statistics will have little effect on the calculated values of the electronic transport coefficients. The calculation of the Lorenz factor and the ratio $\lambda_e/\lambda_L$
are based upon Fermi-Dirac statistics and are valid at high carrier concentrations.

4. Thermoelectric Figure of Merit

The dimensionless thermoelectric figure of merit $ZT$ for a two band model can be written as:

$$ZT = \frac{(\alpha' p' - \alpha_n' \alpha_n')^2}{(1 + \sigma_n' \tau_n' + \sigma_p' \tau_p') \left( \frac{\sigma_n' \sigma_n' (\sigma_n + \sigma_p + \gamma)}{\sigma_n' + \sigma_p'} \right)}$$

where $\alpha'$ and $\sigma'$ are the dimensionless forms of the Seebeck coefficient and electrical conductivity.

V THEORETICAL ANALYSIS

1 Lead Telluride

(i) Relative reduction in thermal conductivity due to phonon-grain boundary scattering.

An estimate can be made of the relative reduction in the lattice thermal conductivity of unalloyed lead telluride with reduction in grain size compared with single crystal material using the model outlined. The results of this calculation are displayed in Figure 1.

**Figure 1.**
Plot $\lambda_L$(sintered)/$\lambda_L$(single crystal) for unalloyed lead telluride at 300K as a function of grain size and level of doping. $k_0 = 1.0$, $A = 0$; curves: 1, $B = 0.050$; 2, $B = 0.010$; 3, $B = 0.005$; 4, $B = 0$.

Although there is some difficulty in making an accurate prediction of the dependence of the lattice thermal conductivity on the various parameters because of a lack of experimental data and the uncertainty in the appropriate value of $k_0$ it is possible to estimate the range over which the results will vary. In undoped lead telluride the reduction in lattice
thermal conductivity is given by \((1 - \frac{\lambda_{\text{sintered}}}{\lambda_{\text{single crystal}}}) \times 100\) for a mean grain size of \(1\mu m\) is around 6 percent. For doped lead telluride \((10^2 m^{-1} - 10^4 m^{-1})\) this reduction is decreased to about 5 percent.

(ii) The ratio \(\lambda_e/\lambda_L\) and the Lorenz factor \(\xi\)

Of central importance in a quantitative evaluation of the figure of merit is the contribution to the thermal conductivity which arises from charge carriers. This contribution \(\lambda_e/\lambda_L\) can conveniently be expressed in terms of the quantity \(\sigma'\xi\). The calculated values of the ratio \(\lambda_e/\lambda_L\) and the Lorenz factor are displayed in Figure 2 as a function of the reduced

![Figure 2](image)

**Figure 2.** The ratio \(\lambda_e/\lambda_L\) and the Lorenz factor \(\xi\) as a function of reduced Fermi energy \(\xi\) for lead telluride at 300K. ![Figure 3](image)

**Figure 3.** The ratio \(\lambda_e/\lambda_L\) as a function of reduced Fermi energy \(\xi\) for lead telluride at different temperatures. A non parabolic energy band is considered with \(B_\gamma = k_B T/E_g\); acoustic phonon scattering. Curves (A) 300K (B) 500K (C) 700K (D) 900K.
Fermi energy ($\xi$) for parabolic and non parabolic bands. Scattering of electrons by acoustic and optical modes have been included. Important material parameters for lead telluride are collected in Table 1. In Figure 3 is displayed the ratio $\lambda_e/\lambda_L$ versus $\xi$ for lead telluride at different temperatures for a non parabolic energy band. The temperature variation of $\beta_g$ is obtained from the relationship $\beta_g = k_B T / E_g$. The Lorenz

$\lambda_e/\lambda_L$ for PbTe corresponding to $\xi_{\text{opt}}$ at different temperatures is presented for parabolic and non parabolic energy bands. Carrier scattering has been taken to be by acoustic phonons only.

</table>

It is apparent from Figure 2 that the ratio $\lambda_e/\lambda_L$ corresponding to a particular value of $\xi$ is considerably reduced when the effect of non parabolicity is taken into account. In thermoelectric applications the behaviour of the material in the region of $\xi_{\text{opt}}$ (value of the reduced Fermi energy which optimises the thermoelectric figure of merit) is of considerable interest. In Table 2 the ratio $\lambda_e/\lambda_L$ for PbTe corresponding to $\xi_{\text{opt}}$ at different temperatures is presented for parabolic and non parabolic energy bands. Carrier scattering has been taken to be by acoustic phonons only.
The inclusion of non-parabolicity in the calculation of both scattering mechanism considerably reduces the electronic contribution to the thermal conductivity. The calculated value of the combined scattering is in very good agreement with the experimentally obtained values. Combining the effect of the two scattering mechanisms is not straightforward. A rough estimate can be obtained by assuming $\tau$ at $t_{opt}$ to be the same for both cases; the inverse electrical conductivities can
then be added to give the combined values.

In Figure 5 are displayed the calculated values of the electronic thermal conductivity of n-type lead telluride

\[ \lambda_e \]

Figure 5. Electronic thermal conductivity \( (\lambda_e) \) for n-PbTe as a function of carrier concentration and temperature (acoustic scattering and non-parabolic bands). Curves 1, 2, 3, 4 correspond to temperatures of 300, 450, 600, 750K, respectively.

Figure 6. Electronic thermal conductivity \( (\lambda_e^{\text{optical}}) \) versus carrier concentration. Curves 1, 2, 3, 4 correspond to the temperatures of 300, 450, 600, 750K, respectively.

as a function of carrier concentration at temperatures of 300, 450, 600, and 750K assuming that the electrons are scattered by acoustic phonons. At carrier concentrations \( 10^4 \text{m}^{-3} \) the electronic contribution becomes dominant; consequently the contribution due to polar optical scattering (Figure 6) should be included in the calculation of \( \lambda_e \).

(iv) Total Thermal Conductivity

A reasonable estimate of the temperature variation of the total thermal conductivity can be obtained by assuming a temperature dependence of \( 1/T \) for the lattice thermal conductivity. The results of this calculation are plotted in Figure 7 assuming acoustic phonon scattering. In Figure 8 the total thermal conductivity is plotted as a function of
temperature for two different carrier concentrations; \( n = 5 \times 10^2 \) cm\(^{-3}\) and \( 10^3 \) cm\(^{-3}\). Curves 1 and 2 correspond to acoustic phonon scattering and include the effect of non-parabolic energy bands. Curves 1' and 2' are the total thermal conductivity with \( \lambda_e \) given by \( \lambda_e^{-1} = \lambda_e^{(\text{acoustic})} + \lambda_e^{(\text{optical})} \). Evidently the inclusion of polar optical scattering has

![Figure 7](image)

![Figure 8](image)

**Figure 8.** Total thermal conductivity \( \lambda \) versus temperature. 1,1'-5 \times 10^2 \) m\(^{-3}\); 2,2'-10^2 \) m\(^{-3}\); 1',2' include scattering of electrons by polar optical modes along with the acoustic modes. Experimental points by Efimova et al. [13]: \( \Delta 5 \times 10^2 \) m\(^{-3}\) and \( \blacksquare 10^2 \) m\(^{-3}\).

an appreciable effect on the total thermal conductivity at carrier concentrations in excess of \( 5 \times 10^2 \) m\(^{-3}\). The calculation of the lattice thermal conductivity in Figure 8 also takes into account the scattering of phonons by free electrons. The parameter B was adjusted to the values of 0.01 and 0.02, curves (1,1') and (2,2') respectively. Excellent agreement is obtained between the calculated values and reported experimental data at around room temperature. However, it is apparent that the slopes of the theoretical curves are somewhat greater than those based upon experimental data. The inclusion of a photon contribution to the thermal conductivity at higher temperatures is likely to be small for doped samples and is unlikely to account for the differences in slope. In
Figure 9 is displayed the effect of phonon-grain boundary scattering on the room temperature thermal conductivity of small grain size lead telluride. Earlier calculations of this effect did not take into account the electronic contribution to the thermal conductivity.

![Figure 9](image.png)

Figure 9. Total thermal conductivity versus carrier concentration for "single crystal" lead telluride and fine-grained material with mean grain size 1μm.

The calculation assumes an absence of disorder ($A=0$) and consequently the reduction in thermal conductivity corresponds to the situation when boundary scattering is relatively less effective in scattering phonons. In undoped lead telluride with a mean grain size of 1μm the reduction in thermal conductivity will be about 6% whereas in the range of optimum doping encountered in thermoelectric applications ($n=2x10^24 m^{-3}$ in lead telluride) this reduces to about 5%.

2. Disordered Lead Telluride
   (i) Introduction

As mentioned previously, phonon-grain boundary scattering will be enhanced in alloys. The initial theoretical model, which was developed to obtain an estimate of the relative reduction in the lattice thermal conductivity of lead telluride with decrease in grain size, was extended to include disordered lead telluride (alloys). An estimate was obtained of the dependence of the thermal conductivity and thermoelectric figure of merit on grain size, level of doping for a highly disordered alloy. Preliminary calculations indicated that calculations involving relative changes in the thermoelectric figure of merit are fairly insensitive to the inclusion of refinements in the theoretical model. A two band model with a parabolic multivallied structure was considered, acoustic scattering was taken as the dominant scattering mechanism, intervalley scattering was neglected and no distinction made between conductivity effective mass and the density of states effective mass.
(ii) **Reduction in the lattice thermal conductivity**

Plots of the ratio $\lambda_{\text{sintered}}/\lambda_{\text{single crystal}}$ at room temperature for highly disordered alloys of lead telluride ($A=5$) is displayed in Figure 10 as a function of grain size and level of doping; in material with a mean grain size of about 1$\mu$m the reduction in lattice thermal conductivity compared to equivalent single crystal material is in the range 11-13 percent.

**Figure 10.** Plot of $\lambda_{\text{sintered}}/\lambda_{\text{single crystal}}$ for a highly disordered alloy of lead telluride of grain size and level of doping. $k_0$ = 1.0, $A=5.0$; curves 1, $B=0.050$; 2, $B=0.010$; 3, $B=0.005$; 4, $B=0$

(iii) **Effect of small grain size on the thermoelectric figure of merit.**

As indicated in Table 2 preliminary calculations of the thermoelectric figure of merit ($Z$) of unalloyed lead telluride indicated that $Z$ was optimised at room temperature at a reduced Fermi Energy ($\xi$) of $-0.75$; which corresponded to a carrier concentration of about $2 \times 10^{24} \text{m}^{-3}$. The thermoelectric figure of merit for a highly disordered alloy of lead telluride at their different carrier concentrations around optimum doping
is shown in Figure 11 as a function of temperature. The temperature
dependence of the effective mass $m^*$ and the energy gap $E_g$ is taken into
account using the relationship

$$\frac{1}{m^*} \frac{dm^*}{dT} = \frac{1}{E_g} \frac{dE_g}{dT}$$

$$E_g(T) = E_g(T_0) - \frac{dE_g}{dT} (T-300)$$

with $T_0 = 300K$, $dE_g/dT = 4 \times 10^{-4}$, $m^* = 0.2m_0$ at 300K, $\lambda_L$ at 300K is
1.70Wm$^{-1}$K$^{-1}$ and is assumed to vary inversely with temperature. The
variation of carrier concentration $n$ with temperature is obtained by
relating the variation of Seebeck coefficient with reduced Fermi
potential to the temperature dependence of the Seebeck coefficient for
various carrier concentrations. In Figure 11 a comparison is drawn
between "single crystal" and small grain size material. It is evident
that the thermoelectric figure of merit of highly disordered lead
telluride type material with a mean grain size of ~1µm is about 10 percent
higher than equivalent "single crystal" or large grain size material.

3. Alloys based upon lead telluride

(i) Introduction

A realistic theoretical model for lead telluride, which included a
multivalled structure, intervalley and intravalley scattering, non
parabolic energy bands, acoustic phonon and optical phonon scattering; has
been developed and close agreement obtained between theoretical and
measured transport properties. This model was then employed in
identifying alloys based upon lead telluride with the highest potential
for improvement in their figure of merit as a result of phonon-grain
boundary scattering. PbSnTe and PbGeTe are particularly favoured because
large differences in atomic masses of the constituent atoms give rise to
substantial alloy disorder scattering and these materials were
investigated.

(ii) Reduction in the lattice thermal conductivity of PbSnTe and PbGeTe.

The results of calculating the ratio $\lambda_L(\text{sintered})/\lambda_L(\text{single crystal})$
as a function of grain size $L$, conveniently expressed in terms of a
parameter $D$ where $D = CT$ and $T$ is the absolute temperature for PbSnTe and
PbGeTe are displayed in figures 12 and 13.
Figure 12. $x$, the ratio $\frac{\lambda_L(\text{sintered})}{\lambda_L(\text{single crystal})}$, plotted as a function of the parameter $D$ and grain size $L$ for PbTe-SnTe at 300K. Curve I, $B=0$ (undoped); curve II, $B=0.01$ (optimally doped).

Figure 13. $x$, the ratio $\frac{\lambda_L(\text{sintered})}{\lambda_L(\text{single crystal})}$, plotted as a function of the parameter $D$ and grain size $L$ for PbTe-GeTe at 300K. Curve I, $B=0$ (undoped); curve II, $B=0.01$ (optimally doped).

The basic characteristics of the PbTe system has been retained in the calculation and the effect of alloying with SnTe and GeTe is to produce disorder which can effectively scatter the high frequency phonons. This has the effect of enhancing the effectiveness of phonon-grain boundary scattering. Although there is some difficulty in making accurate predictions of the dependence of the lattice thermal conductivity on the various parameters because of a lack of experimental data and an uncertainty in fixing an appropriate value of $k_o$ it is possible to estimate the range over which the results will vary.

It is concluded that in undoped PbSnTe and PbGeTe ($B=0$) with a mean grain size of 0.5$\mu$m at 300K the percentage reductions in lattice thermal conductivity given by \[1 - \frac{\lambda_L(\text{sintered})}{\lambda_L(\text{single crystal})}\] x 100 are 15 percent and 18 percent respectively. In optimally doped material (assuming carrier concentration to be similar to that of unalloyed lead
telluride the reductions are 11 percent and 14 percent respectively. A further reduction in mean grain size to 0.25\(\mu\)m would decrease the lattice thermal conductivity of lead telluride by 17 percent and PbGeTe by 21 percent. This is approaching the limit of the beneficial effect of a reduction in grain size as in this region electron grain boundary scattering becomes significant and leads to an undesirable decrease in the electrical conductivity.

VI EXPERIMENTAL PROGRAMME OF WORK.

1. Introduction

The theoretical model outlined in Section I provided a guide on the reduction in lattice thermal conductivity with decrease in grain size. The objective of the experimental programme of work was to substantiate the theoretical predictions and towards this end it was decided to attempt to prepare compacted material with a mean grain size of <5\(\mu\)m and <0.5\(\mu\)m.

2. Charge material preparation

(i) <5\(\mu\)m grain size

The starting material used in the investigation was a pulled, large grain size (up to 0.5cms) ingot of 2N-lead telluride supplied by Global Thermoelectrics* 2N is a 3M* designation for lead telluride to which approximately 0.03 molecular percent PbI\(_2\) has been added to increase the carrier concentration. The ingot was crushed under methanol in an agate pestle then ground wet for one hour in a two ball vibromill. The powder was sieved through a 5\(\mu\)m British Standard microsieve using methanol as a vehicle and assisted by ultrasonic vibrations.

(ii) <0.5\(\mu\)m grain size

Decreasing the grain size of the charge material by an order of magnitude prescribed handling problems. Submicron size particles are airborne at low velocity draughts and all handling stages of the powder were carried out when wet with methanol. The <5\(\mu\)m grain size sieved fraction obtained as described above was ground in an agate ball mill for one hour using methanol as a vehicle. A photomicrograph of the resultant powder dispersed in NONIDET P42 and viewed in transmitted light is shown in Figure 14. The powder rests on the base of a 5\(\mu\)m aperture microplate.

* Global Thermoelectric Power Systems Ltd
PO Box 400
Bassano
Alberta, Canada
sieve and the operative provides a convenient size comparison for the particles. Considerable difficulty was encountered in satisfactorily dispersing these very small particles even when assisted by ultrasonic vibrations as is evident from the agglomerated appearance. No attempt was made to measure the size of the particles, but evidently the vast majority of particles are less than 0.5 μm. The charge is introduced into the die as a "slurry" and the methanol evaporated off in situ.

3. Hot Press

It is reported in the literature\textsuperscript{27} that lead telluride can be successfully compacted using hot or cold pressing techniques. However, lead telluride is known to possess a relatively high vapour pressure and losses of constituents result in a change in transport properties; consequently initial attempts were made to cold compact the powders. The arrangement employed in this present study is shown in Figure 15. A cold compaction pressure of 300 MPa is recommended, consequently emphasis was placed on strength and stability with the die and supporting column machined in a number of interlocking sections. Provision for rapidly heating the die is made by locating the die inside a relatively large graphite cylinder. The die and plungers are fabricated from TZM alloy and machined to a press fit. The inside surface of the die is painted with liquid graphite and the faces of the plungers separated by high density graphite spacers.
4. Pressing procedure

A series of cold compactions were carried out on <5μm powder over a wide range of pressures. Single crystal density is 8.25 gm cm\(^{-3}\) and the density of the compacts increased with pressing pressure from 5.0 gm cm\(^{-3}\) at 150 MPa to 7.80 gm cm\(^{-3}\) at 400 MPa as shown in Figure 16. Although it should be noted that this graph is only a guide as its shape is strongly dependent upon the state of the particle surface and particle size.
Cracks develop in compacts pressed at >300 MPa and they invariably break into sheet-like pieces in planes perpendicular to the pressing direction. The application of heat greatly reduces the required compaction pressure. Mechanically strong compacts with a grain size of <0.5 μm and densities of around 8.1 g cm$^{-3}$ were prepared by hot pressure sintering for 10 minutes at a pressure of approximately 100 MPa and a temperature of 1100K. Compacts of similar densities were also prepared with a grain size of <0.5 μm, although these compacts were not as mechanically strong. As the main objective of this stage of the research programme was to determine the change in thermal properties with grain size rather than evaluate the effect of high temperature compaction on the electrical properties of PbTe, subsequent physical characterisation and measurement of transport properties were made on hot pressed, high density compacts.

*Figure 17. Photomicrograph of <0.5 μm grain size compacted lead telluride.*
5. Physical Properties

The surface of the high density, pressed discs, after polishing down to \(1/12\mu m\) size is smooth and void free when examined by optical microscopy. The grain structure of the compact is revealed by heating in an iodine etch at 368K for 5 minutes \((10H_2O, 5gm NaOH and 0.2gm I_2)\). A photomicrograph of <0.5\(\mu m\) grain size compacted material is shown in Figure 14. It is apparent that the "larger grains" are agglomerates and that little, if any, grain growth has taken place. Density of the compacts were determined by the method of hydrostatic weighing. Error in density determination is less than 0.5 percent.

(i) Introduction

The transport properties, and in particular the electrical properties, are determined by the stoichiometric ratio of its components. An excess of lead induces n-type electrical behaviour and an excess of tellurium, p-type by behaviour, carrier concentration of about \(3\times10^{23}m^{-3}\) can be induced in this way. In thermoelectric application carrier densities an order of magnitude larger are required than those which can be achieved by changing the stoichiometric ratio. These higher values of carrier concentration are obtained by introducing foreign molecular species such as \(PbI_2\) (electrons) and Na (holes). The solid solubility limit of the components are temperature dependent and is determined by the annealing temperature. The carrier concentration also depends upon the rate of quenching with more carriers remaining in solution if the material is rapidly quenched.

(ii) Seebeck coefficient and electrical resistivity measurements.

Seebeck coefficient measurements were made using a hot probe; accuracy of measurement is \(\pm 3\) percent. Electrical resistivity measurements were made using the four probe method; accuracy \(\pm 2\) percent. Measurements of Seebeck coefficient and electrical resistivity were made on the pressed compacts and compared with values obtained from measurements on discs having identical geometry and cut from the original "single crystal" ingot. The Seebeck coefficient and electrical conductivity of "as compacted" material differs considerably from that of single crystal. High temperature annealing is an established procedure for stabilizing the transport properties of semiconductors and the compacted materials have been subjected to a variety of annealing sequences. The effect of rapidly cooling the sample (quenching in water) is to "freeze in" the large number of carriers present at the higher...
temperature and hence reduce the Seebeck coefficient. Rapid cooling, however, is accompanied by an increase in the strain energy of the sample, and results in a decrease in the carrier mobility and consequent increase in resistivity. To date electrical properties closest to single crystal have been obtained by annealing the compact in an argon atmosphere at 1040K for 3 hours followed by 4 hours at 700K and slowly cooling to room temperature. Seebeck coefficients very close to that of single crystal have been obtained whilst the electrical conductivity, although substantially reduced, remains significantly higher than single crystal value.

(iii) Thermal diffusivity and thermal conductivity measurements.

Room temperature thermal diffusivity measurements were made on hot pressed samples using a laser flash technique. Discs 5mm in diameter were cut from the <5um compacted material using an ultrasonic drill. Thermocouple contacts to the rear of the sample are made using pressure contacts. Optimum sample thickness for thermal diffusivity measurements was about 1mm, but samples of this thickness were too fragile and invariably fractured when subjected to the contacting pressure which was necessary to provide low electrical resistance contacts. Consequently samples 2mm thick were employed. As indicated previously compacts of <0.5mu grain size material were relatively weak and proved difficult to machine. Thermal conductivity measurements were made on the polished surface of these very small grain size samples. A suitable disc thickness is 1cm. A thermal comparator method was employed and again a comparison made between the compacted sample and one of identical geometry.

Figure 18. The reduction in thermal conductivity of PbTe with decrease in grain size (L) - optimally doped........... undoped (theoretical curves) • Experimental values.
cut from the "single crystal" ingot. The reduction in thermal conductivity with decrease in grain size (at room temperature) is shown in Figure 15.

vi Discussion and conclusion

All principle objectives of the programme of research have been achieved. A semiquantitative theoretical model of lead telluride has been used to estimate the relative reduction in lattice thermal conductivity, compared to that of single crystal, which accompanies the use of small grain size material. It was predicted that in material with a mean grain size of 1µm, the reduction would be around 5 percent. A procedure has been developed for comminuting very small grain size material and a number of high density compacts of lead telluride successfully prepared. Measurements on small grain size compacts substantiated the predicted reduction in thermal conductivity with decrease in grain size.

A realistic theoretical model has been developed for lead telluride. Very good agreement was obtained between the theoretical values of the thermal conductivity and experimental values cited in the literature. The thermoelectric figure of merit is optimised at a carrier concentration of about 2x10^2 m^-3. Provided the electrical properties can be maintained close to "single crystal" value the thermoelectric figure of merit in highly disordered alloys of lead telluride with a mean grain size of ~1µm and optimum doping is calculated to be about 10 percent higher than equivalent single crystal values.

The model has been used to explore the thermal properties of alloys based upon lead telluride. PbSnTe and PbGeTe hold out the best potential for improvement in the figure of merit, as a result of a decrease in the lattice thermal conductivity due to phonon-grain boundary scattering. At room temperature the lattice thermal conductivity of PbSnTe and PbGeTe, optimally doped and with a grain size of 0.25µm, would be reduced by 17 percent and 21 percent respectively.

Although not strictly part of this current research contract, the behaviour of the electrical transport properties of fine grained compacts is very relevant to any attempt to improve the thermoelectric figure of merit. The results of a limited programme of work in this area indicate that Seebeck coefficients very close to single crystal values can be obtained by annealing the fine grain compacted material. Electrical resistivity values can also be substantially reduced although values remain significantly higher than equivalent single crystal values. A systematic investigation is required to establish the annealing procedure
which optimises the electrical properties of these compacts.

It is concluded that the thermal conductivity of lead telluride type material can be substantially reduced and hence the thermoelectric figure of merit significantly improved through the use of very small grain size material, provided the electrical properties can be maintained at values close to those of equivalent single crystal material. As annealing procedures are routinely employed in controlling the electrical properties of established thermoelectric materials it is not anticipated that the development of a suitable annealing procedure for very fine grained lead telluride type material would present great difficulties.

VIII ACKNOWLEDGMENTS

Dr C M Bhandari is thanked for his contribution to this project and the United States Army, under Contract No. DAJA 45-84-C-0029, is acknowledged for supporting this work and Dr Bhandari's Visiting Research Fellowship. Global Thermoelectrics is acknowledged for providing the lead telluride material and Mrs Kathleen Edwards of the Department of Physics, Electronics and Electrical Engineering, UWIST, is thanked for typing the manuscript.
REFERENCES

Erratta Detected After Publication
by $D=CT$ where $T$ is the temperature. $A=O$ corresponds to unalloyed material with no disorder present, $B=O$ corresponds to undoped material and $C=O$ to single crystal material. In general $\lambda(A,B,C=0) = \lambda_{\text{single}}$ represents the lattice thermal conductivity of a doped single crystal alloy while $\lambda(A,B,C) = \lambda_{\text{sintered}}$ represents the lattice thermal conductivity of a compacted (sintered) alloy.

3. **Electronic contribution to the thermal conductivity**

(i) **Introduction**

Lead telluride and its alloys possess a narrow energy band gap ($E_g$). These materials have small electron effective masses and the density of states which varies as $m^*{1/2}$ is also relatively small. Consequently a relatively small number of carriers will be sufficient to fill the bands up to high energy levels. The effective mass of electrons near the top of the conduction band become energy dependent. In the model adopted a two band conduction band is considered with the following main features: the band extrema for the conduction and valence bands are assumed to be located at the same $k$ value. The energy separation from the other bands at this $k$ value is greater than the main energy gap and the momentum operator has non-zero matrix elements between the states corresponding to the extremal points. Non-parabolicity and the effective mass of both bands are defined by the interaction of the electron and hole bands only. The energy dispersion law is of the form:-

$$ \frac{n^2k_T^2}{2m_{TO}^*} + \frac{n^2k_L^2}{2m_{ho}^*} = E \left(1 + \frac{E}{E_g} \right) $$

$k_T$ and $k_L$ are the transverse and longitudinal components of the wave vector and $m_{TO}^*$ and $m_{ho}^*$ are the components of the effective mass tensor near the band extremum. This is usually referred to as the "Kane model". The energy dependence of the effective mass is given by :-

$$ m^* = m_{ho}^* \left(1 + \frac{2E}{E_g} \right) $$
where \( L_n(A,B,C) = \int_0^1 \frac{x^n dx}{Ax^4+Bx^2+C} \)

here \( x = \frac{\hbar \omega}{k_B T} \) and \( k_o = \frac{\tau_U}{\tau_N} \) is the ratio of the phonon relaxation times for Umklapp and Normal processes, \( k_B \) is Boltzmann's constant and \( T \) is the temperature. There is no advantage in this present study to undertake detailed calculations of the contributions to the thermal conductivity from separate polarizations and an average acoustic branch is assumed. The various phonon relaxation times are as described in the literature; \(^{14,16-17}\) the phonon-electron scattering relaxation time is given by

\[
\tau_{pe}^{-1} = B'x
\]

\( A, B \) and \( C \) are given by

\[
A = \frac{\pi \rho v_s \lambda_o \omega D}{2 \sqrt{3} k_B \left( 1 + \frac{5k_o}{9} \right)} \quad \text{Alloy disorder scattering}
\]

\[
B = \frac{2n^2 \lambda_o \lambda B'}{k_B \lambda D (1 + \frac{5k_o}{9})} \quad \text{Free carrier scattering}
\]

\[
C = \frac{2n^2 \lambda_o v_s^2}{k_B \lambda D (1 + \frac{5k_o}{9})} \quad \text{Grain boundary scattering}
\]

The various parameters have the same meaning as in the literature\(^{14,16-17}\). It is usual to express \( C \) in terms of a parameter \( D \), which is inversely proportional to the grain size \( L \) and they are related...
The appropriate expression for \( \tau(\eta) \) which includes the energy dependence of \( M \) is given by\(^{18,20}\)

\[
\tau(\eta)^{-1} = \frac{n k_B T (\rho/N_V)}{\hbar C_1} \epsilon^2 \left[ 1 - \frac{8\beta g \eta (1+\beta g \eta)}{3(1+2\beta g \eta)^2} \right]
\]

where \( C_1 \) is the elastic constant related to the average sound velocity, \( (\rho/N_V) \) is the density of state in a given valley and \( \epsilon \) is the deformation potential constant.

The Lorenz factor is given by:

\[
\lambda = \left[ \frac{2L^u_i}{O_L^{i-2}} \right] - \delta^2
\]

where \( \delta = \frac{1}{L^u_i/O_L^{i-2}} \), and \( n_L^m \) are generalised.

Fermi integrals and defined as:

\[
n_L^m(t) = \int_{\eta_0}^{\infty} \left[ -\frac{\delta t}{\delta n} \eta^n [n(1+\beta g \eta)]^{m(1+2\beta g \eta)^2} \right] d\eta \]

The reduced electrical conductivity is given by:

\[
o' = kN v_{O_L} \frac{T}{(m^*_L L)}
\]

With the carrier concentration \( n \) related to the reduced Fermi energy \( t \), by the expression:

\[
n = \frac{(2m_d^* k_B T)^{3/2}}{3n^2 m_v} \frac{o_L^{3/2}}{n_L^m}
\]

The carrier mobility \( \mu_{ac} \) due to acoustic phonon scattering is given by:

\[
\mu_{ac} = \frac{\text{constant}}{m_c^* m_d^* n_{t}^{3/2} T^{3/2}} \frac{o_L'^{2}}{o_L'^{2}}
\]

3.(iii) Carrier scattering by polar optical phonons

The carrier relaxation time for scattering by polar optical phonons is given by\(^{10}\)
The Lorenz factor is given by:

$$\tau_{\text{op}}^{-1} = \frac{2^{1/2} e^2 k_B T m^* \xi^{1/2}}{\hbar^2 (nk_BT)^{1/2}} \frac{(\epsilon_{\omega}^{-1} - \epsilon_0^{-1})}{(1 + 2\beta g_n^2)} \left[ \ln \left( 1 + \frac{2\beta g_n (1 + \beta g_n)}{(1 + 2\beta g_n)^2} \right) \right]$$

where $
\xi = \frac{1}{L_2^2 \omega_0 L_2^2}$

In the calculations, screening effects have not been taken into account. Polar optical scattering although appreciable in lead telluride materials, is not the dominant scattering mechanism. Consequently neglecting screening effects will not substantially affect the overall electronic transport properties.

The reduced electrical conductivity can be expressed as:

$$\sigma' = N_0 K' T^2 f(\Theta_0 / T) m^* \omega_0 L_2^2 / (\lambda_2 \mu)$$.  

with $K' = \frac{4k_B^2}{3e^2 n^2 \hbar (\epsilon_{\omega}^{-1} - \epsilon_0^{-1})}$

where $\epsilon_0$ and $\epsilon_{\omega}$ are the static dielectric constant and the dielectric constant at high frequencies respectively. $\Theta_0$ is the temperature which corresponds to the optical phonon frequency at the zone boundary.

The carrier mobility $\mu_{\text{op}}$ due to optical phonon scattering is given by:

$$\mu_{\text{op}} = \frac{K'' f(\Theta_0 / T) \omega_0 L_2^2}{T^{1/2} m^* \omega_0 L_2^2}$$

where $K'' = \frac{8\hbar^2 (2nk_B)^{3/2}}{3E(2nk_B)^{1/2}(\epsilon_{\omega}^{-1} - \epsilon_0^{-1})}$

* obtained from calculation of the figure of merit and corresponds to about $2\times 10^4 \text{m}^2/\text{W}^2$.

† $B_g=0.08$ is a realistic estimate of $B_g$ at 300K but because $B_g$ is temperature dependent it becomes less realistic at higher temperatures.

\[ E_g(T) = E_g(300) + 4 \times 10^{-6}(T-300); \quad t_g(T) = E_g(T)/k_B T. \]

* includes intervalley scattering $W_2/W_1 = 0.5$.

Table 3. Room temperature values of the ratio $\lambda_e/\lambda_L$ at optimum doping (non-parabolic energy bands)

† obtained using parabolic bands

(iii) Electronic Thermal Conductivity

The inclusion of non-parabolicity in the calculation of both scattering mechanism considerably reduces the electronic contribution to the thermal conductivity. The calculated value of the combined scattering is in very good agreement with the experimentally obtained values. Combining the effect of the two scattering mechanisms is not straightforward. A rough estimate can be obtained by assuming $t$ at $t_{\text{opt}}$ to be the same for both cases; the inverse electrical conductivities can
