Abstract

A new n-MOS LDD-like device structure (the J-MOS transistor) is proposed. Its design, simulation and fabrication are studied in this paper. N-channel MOSFET's with \( L_{eff} \) below 2\( \mu \)m suffer from high field effects that must be overcome to secure reliable 5 V operation. LDD structures alleviate these effects but their reliability is better than that of conventional MOSFET's only if the \( n^- \) regions have a peak doping density above \( 1 \times 10^{16} \text{cm}^{-3} \). To overcome this limitation and to allow constant voltage scaling for devices into the submicron regime, the J-MOS structure uses a series drain JFET to drop part of the supply voltage. Both 2-D device simulations and experimental results are presented to demonstrate the operation of this device and its potential for applications requiring reliable submicron device operation under maximum supply voltage. The major experimental findings are that the J-MOS structure can sustain 5 V operation even for submicron effective channel lengths. As has been the case with all LDD-like structures, improved device reliability has been achieved at the expense of some performance. However, the advantages of keeping 5 V operation in micron sized devices can outweigh this performance loss.
I. Introduction

Past experience in MOSFET scaling has shown that device design has proceeded under constraints other than those suggested by constant electric field scaling principles [1]. Alternative scaling approaches [2]-[4] have been used instead, which have allowed continued scaling under constant supply voltage. The shrinking of device dimensions while keeping supply voltage constant offers circuit and system performance advantages, in addition to compatibility with the established 5 V standard. This leads inevitably to higher electric fields inside the active regions of the transistors. Operation of micron and submicron MOSFET's in the presence of high field effects has called for innovation in their design so that acceptable device punch-through voltage and long-term device reliability are maintained as MOSFETs are scaled. In particular several LDD-like drain structures with the schematic cross sections of Fig. 1 have been studied and compared for use in VLSI circuits as substitutes for the conventional n+ As-drain. Careful engineering of the drain region in n-channel devices is more important than in p-channel devices, because electrons in Si have a higher impact ionization rate, a lower energy barrier to injection into the oxide at the Si–SiO₂ interface, and saturate their drift velocity at smaller fields than holes. High field effects are then much more deleterious to n-channel device performance and reliability. Since device degradation [5]-[8] is related to heating of carriers as they traverse regions of field strength in excess of 100KV/cm, reducing electric fields at the drain end of the channel is crucial in n-channel devices. LDD designs for submicron p-channel devices have also been proposed [9], mostly for reasons of punch-through prevention.

In both the LDD-FET [10]-[20], and the graded S/D [21]-[27] – or double diffused drain (DDD) – n-channel structures of Fig. 1, the narrow, self-aligned n⁻ regions that are introduced between the channel and the self-aligned n⁺ source-drain are designed to spread the high electric field at the drain pinch-off region into the n⁻ region. Other device structures using a non-self-aligned separate gate, buried channel, or lightly doped S/D have also been proposed [28]-[32]. The reduction and/or spreading of the peak E-field in self-aligned LDD-like structures normally results in an increased reliability insofar as hot electron induced instabilities are concerned. However, if the n⁻ surface doping (Nₛ) is
too light, i.e. $N_s < 10^{18}$ cm$^{-3}$, the LDD-FET’s can actually exhibit poorer reliability than conventional Arsenic-doped $n^+$ S/D transistors in addition to increased series resistance. This LDD related degradation has been shown to be caused by hot carrier injection into the sidewall oxide region [33]-[36] (process (2) in Fig. 2), which in turn leads to excessive series resistance and degradation rates faster than conventional designs [33,34]. At an optimum $n^-$ doping level, process (1) of Fig. 2 should dominate as the longitudinal E-field peaks under the gate. The $n^-$ resistive region of optimized LDD FETs spreads and reduces the peak value of the longitudinal electric field along the channel length, but the $n^-$ region under the sidewall oxide must still remain undepleted for the aforementioned reliability reasons. While peak substrate current is usually reduced with a lighter $n^-$ dose, characteristics of LDD devices can deteriorate more rapidly with $n^-$ doses $< 10^{13}$ cm$^{-2}$ [20,33,34,36,37]. Optimum LDD designs have been studied extensively, and for practical junction depths and S/D furnace anneal temperatures, the optimum $N_s$ is $1 - 2.5 \times 10^{18}$ cm$^{-3}$ [20,38], or, alternatively, the optimum $n^-$ dose is $\simeq 1 - 2 \times 10^{13}$ cm$^{-2}$ for “inside” LDD’s of the type shown in Fig. 1 [36,39,40]. Other studies have proposed that better $I_{SUB}$ and device degradation trade-off for “inside” LDD’s occurs with either a moderately doped ($4 - 10 \times 10^{13}$ cm$^{-2}$) Phosphorous $n^-$ region [41] or with a (shallow As)/(n-$P$) profiled $n^-$ region [42]. Optimum $n^-$ implant doses were determined to be $\simeq 5 - 20 \times 10^{13}$ cm$^{-2}$ for both “outside” LDD’s (Fig. 1-d), which are a double-diffused type of structure self-aligned to the oxide spacer [43], and DDD MOSFET’s (Fig. 1-b) [40,44]. A pseudo 2-D analytical model [45,46] would predict breakdown voltage improvements of less than 2 V and 1 V for DDD and “inside” LDD devices, respectively, in this practical, reliability-proven range of $n^-$ doping levels.

II. JMOS Device Structure

In the search for reliable VLSI MOSFET’s one should recognize the importance of both reducing high fields inside the device, and also keeping high fields as far away as possible from the most sensitive MOSFET region: the Si-SiO$_2$ interface, since most device instabilities are the result of damage to the gate oxide. In the JFET-MOSFET (JMOS) structure
that we have proposed [47], shown in Fig. 3, one seeks to keep the field peak away from the region under the gate, and at the same time force the electron current below the surface in the critical high field region near the drain, which should have the effect of minimizing hot carrier trapping in the gate or sidewall spacer SiO$_2$ regions. Other authors have also shown that LDD's can perform even more reliably by diverting the channel current away from the SiO$_2$ interface in the high field drain region. Techniques proposed to accomplish this include either a buried channel device with a lightly doped drain [48] or a retrograde $n^-$ profile for the LDD region [49]. Other MOSFET device structures have been proposed, like the buried drain D-MOSFET [50], for which the reliability potential in VLSI has not yet been assessed. By construction the JMOS structure avoids the reliability problems found in lighter doped LDD devices associated with carrier injection into the sidewall oxide. Once gate oxide reliability is assured, one is allowed an increase in power supply or a reduction in MOSFET channel length at a given voltage to achieve a performance enhancement. The proposed structure in Fig. 3 has a short channel JFET at the drain end. The JFET physically occurs because of the presence of a $p^+$ region acting as the JFET gate above the $n^-$ drain region (Fig. 3). The $p^+$ implant connects electrically to the substrate by overlapping the channel stop implant in the transverse direction. The circuit model for such device is shown in Fig. 4. The JFET under the sidewall oxide is fully merged into the MOSFET structure and does not require extra silicon area. It does require a minimum of one extra mask in the process.

III. Device Simulation

The JMOS circuit model of Fig. 4 was simulated using SPICE and the transfer function $V_D$ vs. $V_D$ is plotted in Fig. 5, where $V_T$ is the JFET threshold voltage, $V_D$ is the effective drain bias on the intrinsic MOSFET, and $V_D$ is the externally-applied drain bias. The HPSPICE MOSFET level 3 and JFET model parameters used are listed in Table I. The simulation suggests that by appropriately choosing the JFET pinch-off voltage $V_p$, the device designer can limit the maximum drain bias across the surface channel MOSFET. Thus, the JMOS device provides a means of minimizing hot carrier problems imposed by
constant voltage scaling [7], since the series JFET can be designed to support part of the drain supply. When the MOSFET channel is conducting current, the inequality:

\[ V_D < (|V_p| - \phi_n - |V_{SUB}|) = V_{SUB} - V_T \]  

holds, where \( V_p \) is the JFET region pinch-off voltage, and \( \phi_n \) is the \( p^+n^- \) junction built-in potential. In practical designs \( V_p, V_T, \) and \( V_{SUB} \) are \( \leq 0 \). Limiting \( V_D \) could also be accomplished, of course, by reducing (most likely to \( 3 - 3.3 \) V) the supply voltage. However, this has important draw backs since such a reduction leads to compatibility problems, to smaller noise margins in circuits, and to reduced \((V_{GS} - V_T)\) MOSFET drive. Less gate drive often implies slower circuits. The presence of a series drain JFET in the JMOS device allows the full supply to be used on the \( V_D \) and \( V_G \) terminals, while the internal voltage of the reliability sensitive node – i.e. the MOSFET drain – is reduced. Conventionally designed micron sized n-MOSFET’s in fact require drain biases of less than 3 V to saturate the channel current in the practical range \( 0 < (V_{GS} - V_T) < 5 \) V, as shown in Fig. 6. This is simply the effect of saturation of the channel electron average velocity \((\langle v \rangle)\). Submicron devices operating in this saturated velocity regime will have a drain saturation current given by

\[ I_{DS, sat} = W \langle v \rangle C_{ox}(V_{GS} - V_T) \]  

where \( \langle v \rangle \cong v_{sat} \) (the optical phonon scattering limited drift velocity for bulk transport).

The drain JFET device, once it pinches off, limits the JMOS current approximately to its first order pinch-off limit \( I_p \) [51]

\[ I_p = WI_{po} \left( 1 - \left( \frac{\phi_n + V_{DI} + |V_{SUB}|}{|V_p|} \right) \right)^2 \]  

\[ I_{po} = \frac{|V_p|}{n \rho_s L_{sw}} \]  

where \( n (2 < n < 3) \) accounts for the non-uniform doping profile in the \( n^- \) JFET channel, \( \rho_s(\Omega/cm) \) is the buried \( n^- \) sheet resistivity, \( L_{sw} \) is the sidewall spacer width – an approximate measure of the JFET effective electrical channel length – and \( V_{DI}(V_{GS}) \) is the gate voltage dependent effective MOSFET drain or effective JFET source voltage, according to the
lumped circuit model proposed to describe the JMOS device. Eq. (3) neglects short JFET channel length effects which are more important when the $n^-$ doping is lighter. The $I_{po}$ value in $Amps/\mu m$ width depends on the technology design of the vertical impurity profile of the drain-JFET, as well as the sidewall spacer width.

The J-MOS device was simulated by the PISCES 2-D program [52,53] coupled to impurity profiles simulated in 1-D by SUPREM-III [54]. 2-D device simulations have been widely used as useful tools to guide and better understand the design of LDD devices [55]. Fig.7 shows the equipotential contours for the JMOS device under a bias condition in which the JFET under the sidewall oxide is in its linear region of operation. In this mode, the $n^-$ region behaves as a series pinched resistor, or as a buried LDD structure. For the bias condition of Fig. 8, however, the saturation properties of the drain JFET are illustrated. For those biases in which the JFET is ON and pinched off, i.e.

$$(V_{DS} - V_{SUB}) \geq |V_{Tf}|$$

the saturated JFET limits the current in the device to the value of $I_p(V_Gs)$ given by Eq. (3). For the simulated device of Fig. 8 $V_{Tf} = -1.6 \, V$, $V_{DS} = 5 \, V$, $V_{SUB} = 0 \, V$. The JFET pinch-off region then supports most of the 5 V drain bias on this particular JMOS design, while the surface channel MOSFET supports less than 1 V. As suggested by the simulated field pattern under the SiO$_2$/Si interface, and as we shall demonstrate experimentally, this will result in a large reduction in impact ionization under the MOSFET gate. The electron and net donor densities, and the electrostatic potential along the JMOS interface $A - A'$ are shown in Fig. 9-a and Fig. 9-b, respectively, for $V_{GS} = 1 \, V$, $V_{DS} = 5 \, V$, $V_{SUB} = -1 \, V$. The peak longitudinal E-field at the gate SiO$_2$/Si interface is kept below $5 \times 10^4 \, V/cm$, which is one order of magnitude smaller than typical peak fields at the drain-end of pinched off conventional MOSFETs [56]–[58].

PISCES simulated I-V characteristics are shown in Fig. 10 for the device of Fig. 8. In this JMOS device the onset of saturation is independent of $V_{GS}$ since the drain-JFET pinches off at the drain voltages for which Eq. (5) is an equality. In this case the JFET operates as a current-limiting device fully merged into the LDD region. The PISCES simulated transfer function ($I_p/W$) vs. $V_{GS}$ is shown in Fig. 11, where $I_p$ is the pinch-off
current of Eq. (3). A JFET short channel effect is responsible for the output conductance in Fig. 10 and the variation of $I_p(V_{GS})$ with $V_{DS}$ in Fig. 11. This effect is quite easily seen in Fig. 8 as the drain field encroaches under the entire length of the $p^+$ JFET gate. Fig. 12 shows the same device under bias conditions that turn the JMOSFET off through the application of substrate bias, while the MOSFET surface is strongly inverted. In the case illustrated, $V_{GS}=V_{DS}=5V$ and $(V_{SB}-V_{DI}) \leq V_T$, i.e. the drain-JFET region is OFF and the MOSFET is ON. Thus, it is possible to turn off all JMOSFET’s on a chip through appropriate substrate bias.

These device simulations have demonstrated the basic operation of the device. A variety of such simulations were used to suggest structural variations to optimize device performance. Control over the encroachment of high fields under the gate of the MOSFET can be achieved through proper design of the LDD region by adjusting the pinch-off voltage of the JFET region, $V_p$, to maximize device current drive while keeping short channel effects, and hot carrier injection into the gate oxide under tolerable limits.

**IV. Device Fabrication**

The fabrication process used is a standard 2$\mu$m n-MOS process using LOCOS isolation, a 400 Å gate oxide, and $n^+$ polysilicon gates. The starting material was (100), 20–25Ω-cm, boron doped silicon. A 900 Å $\text{Si}_3\text{N}_4$ on 400 Å $\text{SiO}_2$ mask was used during the local oxidation. The boron field implant dose was $1.5 \times 10^{13}\text{cm}^{-2}$ at 120KeV. The field oxidation was done in steam at 1000°C/200 min.

Both conventional n-MOS devices and LDD n-MOS devices with 5 different variations in the source-drain regions were fabricated side by side, to test experimentally the JMOS device alongside the other better known LDD-MOSFET’s. The major JMOS fabrication steps are shown in Fig. 13. By suitable combinations of the masked implants, all drain structures, including symmetrical JMOS and larger geometry JFET’s, were fabricated side by side on the same chip. The asymmetric JMOS structure of Fig. 3 can be fabricated with only one extra masking step in addition to the conventional NMOS process if one
were to choose an LDD-type source structure and a drain JFET structure. Lightly doped source structures should either be doped above $5 \times 10^{18} \text{cm}^{-3}$ or be avoided altogether if transconductance reduction due to series source resistance [59]–[62] is to be kept low. Lighter doping levels are necessary on the drain, however, if one seeks to reduce the drain high field problem. In this work, 3 different $n^-$ Phosphorous implant doses were used. Simulated surface concentrations for the $n^-$ region were $8 \times 10^{17} \text{cm}^{-3}$ for a low $V_p$ JFET, $2 \times 10^{18} \text{cm}^{-3}$, and $3 \times 10^{18} \text{cm}^{-3}$ for higher $V_p$ JFETs, after a 1050°C, 60 min. drive-in of the Phosphorous implant. A shallow 100 KeV $p^+$ BF$_2$ implant followed to form the substrate-connected JFET gate on the JMOS devices. The 1050°C anneal assured sufficient lateral diffusion of the $n^-$ implant to guarantee merging of the surface MOSFET channel and the JFET channel after the $p^+$ and $n^+$ implant anneals that followed. LDD region definition was done with a conventional sidewall spacer technology [63]–[64] by depositing 8,000 Å LPCVD oxide, followed by a 900°C/30 min. oxide densification, and oxide plasma etch. Final sidewall oxide spacer widths of 4,100 to 4,600 Å were obtained. Subsequently, conventional $n^+$ As S/D implant and a 900°C/30 min. anneal followed. SUPREM-III simulated profiles after all anneals for the high $V_p$ and low $V_p$ JFET designs, as well as for the $n^+$ As drain profile are shown in Fig. 14. Final MOSFET channel region boron surface concentration was $1.3 \times 10^{16} \text{cm}^{-3}$. Table II summarizes the relevant parameters for the two JMOS designs to be mentioned.

V. Experimental Results

A. I–V Characteristics

Fig. 15 shows the log($I_{DS}$) – $V_{GS}$ characteristics for the low–$V_p$ JMOS device at $V_{DS} = 0.1$ V, in which both the JFET subthreshold and the MOSFET subthreshold regimes are illustrated. The drain current exhibits the usual exponential turn-on [65] in the MOSFET subthreshold regime. However, due to the drain JFET gating action, the drain current can be turned-off by setting $V_{SUB} < V_T$. For this low-$V_p$ design $V_T = -(|V_p| - \phi_w) = -0.8$ V. The long channel, zero backgate bias MOSFET threshold voltage is 0.32 V, as extracted by
the TECAP2 [66] fitting of the conventional device linear region $I_{DS} - V_{GS}$ characteristics at several substrate biases. Fully extracted conventional MOSFET parameters are shown in Table I.

A $(W/L) = (50/5)$ JMOS device is compared to a conventional MOSFET of the same drawn gate length in Fig. 16. The JMOS effective channel length is $\approx 0.2 \mu m$ shorter than its conventional counterpart on the same chip. At large $V_{GS}$ the value of $I_p$ given by Eq. (3) saturates to a value $I_{p_{sat}}$ experimentally determined for devices with $L_{gate} = 2 \mu m$. This saturated value of the JMOS $I_{DS}$ for $V_{SUB} = 0V$, $V_{GS} = V_{DS} = 5 V$ is $I_p = 24 \mu A/\mu m$, and is practically independent of MOSFET intrinsic channel length or polysilicon gate bias, so that the JFET acts as a current limiter in the device structure. This value compares reasonably well with the simulated value $I_{DS_{sat}} = 37 \mu A/\mu m$, for a narrower sidewall spacer, and hence a shorter JFET length. The degree of current limiting by the JFET in this low-$V_p$ design is more than what would be desired in an actual VLSI application but its characteristics are shown here to illustrate the JFET action as the two active devices are merged.

The $I_{DS} - V_{DS}$ characteristics of JMOSFET’s with higher $V_p$ are compared to their conventional counterparts on the same chip in Figs. 17-18. These JMOSFET’s have $I_{p_{sat}} = 200$ and $320 \mu A/\mu m$ width, respectively. $I_{p_{sat}}$ for the high-$V_p$ design of Fig. 18 is larger than the $5 V$ current drive capability of our conventional enhancement n-MOS devices built with a $400 \AA$ gate oxide, $2 \mu m$ technology. Hence, for large $V_{DS}$ bias, short channel MOSFET, the JMOSFET saturation current limit is given by velocity saturation of the MOSFET inversion carriers, according to Eq. (2). In the high-$V_p$ case, as shown in Fig. 18, the $I_{DS_{sat}}$ values are the same for both conventional and JMOSFET devices. In this case the operation of the drain-JFET is in its linear region, and the device acts as a simple buried LDD. This has the effect of increasing the linear region ON resistance of the JMOSFET. Drain series resistance for this case was extracted to be $10K\Omega - \mu m$ in excess of the conventional transistor series resistance, by using the measurement procedure of [67]. Based on measured sheet resistivity data for large geometry $n^-$ pinched resistors, one concludes that the $n^-$ buried LDD contribution to the series drain resistance does
not account for such series resistance increase. We believe that a sizable contribution to this ON resistance of the high \( V_p \) JMOSFET comes from the contact resistance of the Al(1\%Si) metallization to the \( n^+ \) drain diffused layer which is compensated by the high dose \((2.2 \times 10^{14} \text{ cm}^{-2})\) \( p^+ \) JFET gate implant. Further improvements of this device structure are necessary to address two detrimental effects of including a shallow \( p^+ \) implant into the drain \( n^- \) region: first, the low breakdown voltage of the \( p^+ \) substrate/\( n^+ \) drain junction; second, increased ON resistance due to impurity compensation of the surface \( n^- \) region; and third, the effect of the compensated \( p^+ \) layer on the contact resistance of the metal to \( n^+ \) region. These limitations can be overcome by more optimum design of the doping profiles in the drain region.

The 1050°C \( n^- \) drive-in step results in a fairly deep \( n^- \) junction in the high-\( V_p \) case, \( \approx 0.7\mu m \) according to the simulation results in Fig. 14. Also, considerable diffusion of the channel implants for \( V_T \) adjustment and punchthrough suppression occurs. Scaling suggests that the S/D junction depths should be kept as shallow as technologically feasible. A JMOS device optimized for technologies with \( L_{\text{eff}} < 1\mu m \) would have to use shallower junctions. The threshold voltage shift in the short channel regime should in turn be controlled by an appropriate choice of \( t_{ox} \) and punchthrough suppression implant dose. For the technology choices in this experiment, all devices had a linear region short-channel \( V_T \) shift of less than 100mV down to \( L_{\text{eff}} = 1.25\mu m \) as shown in Fig. 19 for conventional (\( \circ \)), high-\( V_p \) (\( \circ \)), and graded S/D (\( \triangle \)) devices. The \( V_T \) measurement used for Fig. 19 assumes that the threshold voltage is given by the linear region \((V_{DS}=0.1 \text{ V})\) extrapolation of the \( I_{DS}-V_{GS} \) curves at the maximum value of transconductance \( g_m = dI_{DS}/dV_{GS} \).

### B. Substrate Current

In Fig. 20 the \( \log(I_{SUB}) \) vs. \( V_{GS} \) characteristics of both a conventional and a low-\( V_p \) JMOSFET (same device as Fig. 16) are compared for devices with the same drawn \((W/L) = (40/16)\). The usual substrate current characteristics [68] are observed for the conventional MOSFET. Its bell-like shape indicates that the substrate current is mostly due to holes generated by impact ionization occurring as carriers traverse the high field region under the gate in the
drain end of the device. The JMOSFET substrate current is mostly independent of gate voltage, it is not triggered by channel current, and it is more than 2 orders of magnitude lower than the peak value of the conventional device $I_{SUB}$. Except for the bias regime in which the conventional MOSFET is well into its linear mode of operation ($V_{GS} > V_{DS}$), i.e. the inversion layer extends from source to drain $n^+$ regions and decreases the longitudinal field strength in the drain end of the channel, the JMOS $I_{SUB}$ is less than the conventional MOSFET impact ionization substrate current.

Drain diodes built on the same chip with different area/perimeter ratio confirmed that the JMOS substrate current shown in Fig. 20 is mostly $p^+/n^+$ sidewall diode leakage. This Zener-like drain–substrate leakage is fairly independent of channel current, hence independent of polysilicon gate length and MOSFET gate bias, and it scales with device width to a typical room temperature value of $\sim 300\, \text{pA}/\mu\text{m}$ at $V_{D-SUB} = 5\, \text{V}$. In JMOS designs with higher $n^-$ and $p^+$ doping densities, the Zener leakage under the same conditions can increase by orders of magnitude when tunneling becomes important, to a typical maximum of $\sim 500\, \text{nA}/\mu\text{m}$ when both sides of the sidewall junction were degenerately doped. High sensitivity to $p^+$ doping levels are expected for shallow $n^+(\text{As})/p^+(\text{Boron})$ junctions with $p^+$-doping levels above $10^{18}\, \text{cm}^{-3}$ [69]. This suggests that an optimum JMOS design must pay careful attention to the $p^+$ doping profile in particular, if substrate current is to be minimized.

C. Gate Current

Very sensitive gate current measurements were done at the wafer level utilizing a floating gate induced drain current relaxation technique demonstrated in [70]. Resolution below $10^{-16}\, \text{A}$ was possible with this technique.

Gate current comparisons presented herein are for devices built side by side on the same chip, since small structural or doping variations can lead to invalid comparisons. Fig. 21 compares the gate current measured as a function of $V_{GS}$ for a conventional, and for the low-$V_p$ JMOSFET of Fig. 16 on the same chip. The former presents the characteristic bell-shaped peak that has been attributed to lucky channel hot carriers (CHE) [7,71], while the
JMOSFET gate current is below the noise level in the measuring apparatus. This extreme reduction of the gate current in the low-\(V_p\) J MOS device can be attributed to the reduction of the internal drain voltage \(V_D\), on the MOSFET due to the presence of the series JFET, even though the external \(V_{DS}\) is 7 V in this measurement. Fig. 21 also presents the gate current of the graded S/D device on the same chip, which gives an indication of impact ionization reduction due to drain profile grading alone. The reduction of the JMOSFET gate current is clearly due to a reduction of \(V_D\), in addition to junction grading. This is consistent with the I-V characteristics of Fig. 16 and the substrate current characteristics of Fig. 20 which indicated that the JFET drain supported most of the drain bias and that impact ionization was negligible under the gate of the low-\(V_p\) JMOSFET, respectively.

Fig. 22 presents the gate current comparison for devices on the same chip of a high-\(V_p\) wafer, measured at \(V_{DS} = 6\) V. Effective channel lengths are 1.25 \(\mu\)m for the conventional MOSFET, and 1.0 \(\mu\)m for the JMOSFET. In the CHE \(I_C\) peak (at \(V_{GS} \approx V_{DS}\)) the reduction provided by the high-\(V_p\) JMOS is relatively small. At lower gate voltages, however, where impact ionization is more intense in conventional devices there is about one order of magnitude reduction in \(I_G\) measured in the JMOS structure. It is clear from Figures 21 and 22 that as the JFET pinch off voltage is reduced, the JFET increasingly limits the overall device current but also increasingly improves the gate current due to hot carriers.

D. Speed Performance

Ring oscillators with Fan-In=Fan-Out=1 were built to benchmark on the same chip the speed performance of the two JMOSFET device designs against conventional designs. The 21 inverter stages were of the n-channel enhancement / depletion type. Depletion and enhancement mode JMOSFET’s were used in the JMOS inverter stages. All ring oscillators had the same drawn geometries: (12/3 drivers, 8/8 loads). Fig. 23 shows the oscillation period as a function of the supply voltage for two wafers. The speed performance of the low-\(V_p\) design (dashed line) is much degraded as compared to the conventional device speed (\(\square\)). This performance degradation is expected since the drive capability of the JMOS inverter stage is severely limited by the low-\(V_p\) drain JFET as shown in Fig. 16.
The high-$V_p$ JMOS ring oscillator had a speed (solid line) comparable to the conventional design on the same chip (o). The slight speed-up for this JMOSFET design is solely attributable to the smaller $L_{eff}$ of the transistors, ($\approx 0.25\mu m$ shorter), and it is within the wafer to wafer variation of the speed performance of the conventional devices. Usually in E/D circuits the average pull-up output current increases sublinearly with supply voltage. For this reason, the larger logic swing at larger supply voltages results in a slow down of the ring oscillator speed as $V_{DD}$ increases, as shown in Fig. 23.

The introduction of the $p^+$ region in the JMOSFET drain has the positive effect of reducing the gate to $n^+$ drain feedback capacitance ($C_{GD}$) at the expense of increasing both drain to substrate junction capacitance ($C_{DSUB}$) and gate to $p^+$ overlap/fringing capacitance ($C_{GSUB}$).

VI. Discussion

The JMOS structures studied have demonstrated the basic advantages of this device design. First, the maximum effective MOSFET drain bias can be set by device design, independently of the maximum externally applied drain and gate bias which can be set at effectively higher voltages. This property is advantageous in view of the pressing need for voltage reduction in conventional submicron MOSFET's brought on by hot carrier effects. Second, the JMOSFET lightly doped drain region can be engineered without the usual reliability constraint imposed on conventional LDDFET's due to hot carrier injection under the sidewall; reliable LDDFET's required $N_S > 10^{18}cm^{-3}$ in the $n^-$ region, while the buried $n^-$ region in the JMOSFET can be more lightly doped to meet the designer's choice for JFET $V_p$. Third, the advantages in channel longitudinal field reduction due to drain junction grading that are common to all LDD-like structures previously studied, are also present in the JMOSFET with the additional advantage of having the channel current driven away from the SiO$_2$ interface in the high-field drain region. All three features combined allow further minimization of charge injection, trapping, and instabilities associated with the gate oxide. Based on the proven correlation between gate and substrate
currents and device reliability found in both conventional and LDD-like devices, we expect submicron JMOSFET's to have good endurance under hot carrier stress.

Our implementations of the JMOSFET have pointed to areas that merit further improvement. First, the breakdown voltage of the sidewall $n^+ p^+$ junction at 6.5 V and the associated junction leakage seen at 5 V render the drain-to-substrate leakage unacceptable for dynamic circuit applications. The use of a phosphorous $n^+$ region self-aligned to the sidewall oxide or a slight ($\approx 0.2 \mu m$) anisotropic silicon etch-back prior to arsenic $n^+$ implant in order to grade or eliminate the $n^+ p^+$ sidewall junction are possible technology implementations that can overcome this shortcoming. Second, a symmetrical JMOSFET suffers from a further effective transconductance decrease due to an increase in series source resistance ($R_s$), since

$$g_{m_{sym}} = \frac{g_m}{1 + g_m R_s}$$ (6)

where $g_m$ and $g_{m_{sym}}$ are the JMOSFET and symmetrical JMOSFET effective transconductances respectively. This likely means that an extra mask must be used to eliminate the $p^+$ region on the source side. Third, process complexity and control are relevant issues in the comparison of the JMOSFET and more conventional designs. The presence of a self-aligned active device under the oxide spacer that controls the current drive of the JMOSFET, makes oxide spacer process control even more necessary. The addition of at least one extra masking step with worst-case alignment tolerance of $L_{gate}/2$ is one additional drawback of the JMOSFET in its asymmetric implementation.

VII. Conclusions

The JMOSFET, a modified LDD device structure has been proposed, designed, modeled and experimentally demonstrated. It provides device designers with tradeoffs in performance somewhat different than LDD devices previously reported. The JMOS device can be optimized for a given technology choice of minimum effective channel length, oxide thickness, and supply voltage. It overcomes some of the reliability problems of LDD devices with peak doping densities below $1 \times 10^{18} \text{cm}^{-3}$ related to injection into the sidewall oxide.
By keeping the longitudinal E-field peak away from the SiO$_2$/Si interface, the JMOSFET structure minimizes hot carrier injection into the oxide – as made evident through gate and substrate current characteristics – and should minimize also the reliability problems associated with that injection. Our results suggest that with proper optimization of the drain JFET this new structure can perform well in VLSI applications, while maintaining its hot carrier resistant properties in submicron 5 V supply circuits. As has been the case with all LDD-like structures, improved device reliability has been achieved at some expense in performance. However, the advantages of keeping the 5 V operation in micron sized devices can outweigh this performance loss.
