We study the limiting behavior of maximum queue lengths in the M/G/1 and GI/M/1 service systems. When the systems are positive recurrent, the distributions of their maximum queue lengths, under standard linear normalizations, either do not converge or they converge to degenerate limits. Consequently, one cannot use classical extreme value theory to characterize their limiting behavior. We show, however, that by varying the system parameters in a certain way as the time interval grows, these maxima do indeed have three possible limit distributions. Two of them are classical extreme value distributions and the third one is a new distribution. The latter distribution is the best one for practical approximations.

ABSTRACT

We study the limiting behavior of maximum queue lengths in the M/G/1 and GI/M/1 service systems. When the systems are positive recurrent, the distributions of their maximum queue lengths, under standard linear normalizations, either do not converge or they converge to degenerate limits. Consequently, one cannot use classical extreme value theory to characterize their limiting behavior. We show, however, that by varying the system parameters in a certain way as the time interval grows, these maxima do indeed have three possible limit distributions. Two of them are classical extreme value distributions and the third one is a new distribution. The latter distribution is the best one for practical approximations.

AMS Subject Classification: 60F05

Keywords and phrases: Extreme values, limit theorems, M/G/1 and GI/M/1 queues, service systems.

1. Introduction

The extreme values of a stochastic process rather than its usual values are often of paramount interest. In a manufacturing plant, for example, a typical concern is the queue length of parts waiting to be processed at a workstation. Small to moderate values of the queue may indicate that the system is operating successfully and fluctuations in the queue are unimportant. On the other hand, large queues may call for extraordinary measures such as the allocation of auxiliary storage space, employee overtime, or rescheduling of production. A natural question is: What is the probability that the queue will exceed a specific critical value in a certain time period? Such questions are the focus of this study. The following paragraphs describe the gist of our results.

Consider an $M/\mu/l$ queuing system in which customers arrive at a single server according to a Poisson process with rate $\lambda$ and the independent identically distributed service times have a mean $\mu^{-1}$. The queue-length process is positive recurrent, null recurrent, or transient according to whether the traffic intensity $\rho = \lambda/\mu$ is below, equal, or greater than $1$, respectively. Let $M_n$ denote the maximum queue length up to the $n^{th}$ time the system becomes empty. We say that $M_n$ has the limit distribution $F$ if there are norming constants $a_n, b_n > 0$ such that

$$\lim_{n \to \infty} P\left( \frac{M_n - a_n}{b_n} < x \right) = F(x),$$

for each continuity point of $F$. If there are no such $F, a_n, b_n$, we say that $M_n$ does not have a limit distribution.

From the classical extreme value theory, as in Galambos (1978) or Leadbetter et al. (1983), we have the following results:
(1.1) If \( \varphi = 1 \), then \( \lim_{n \to \infty} P(M_n / n < x) = e^{-x}, \quad x > 0. \)

(1.2) If \( \varphi < 1 \), then \( M_n \) does not have a limit distribution.

Cohen (1969) proved (1.1) and an analogue for GI/M/1 queues as well. Related results appear in Iglehart (1972) for GI/G/1 queues and in Serfozo (1986) for birth and death processes. Other insights on extremes of queues appear in Heathcote (1965) and Heyde (1971). Anderson (1970) observed the anomaly (1.2) and gave bounds on the distribution of \( M_n \). The result (1.2) is due to the property that if \( M_n \) is the maximum of \( n \) independent integer-valued random variables with distribution \( F \), then \( M_n \) does not have a limit distribution when \( [F(m) - F(m-1)]/[1 - F(m-1)] \) does not converge to \( 1 \); see for instance Theorem 1.7.13 of Leadbetter et al. (1983). The results (1.1) and (1.2) say that the maxima of null recurrent queues have a limit while the maxima of positive recurrent queues do not. This is the reverse of what one would anticipate.

In this paper, we show that maxima of positive recurrent queues are more well behaved than (1.2) suggests. The key idea is that by allowing the basic parameters of the queueing process to vary with \( n \) in a certain manner, then their maxima do indeed have the three limiting distributions shown in (2.1). The first and third distributions are the classical Frechet and Gumbel extreme-value distributions, and the other distribution is a new one. We have shown in Serfozo (1986), that the maxima of positive recurrent birth and death processes and M/M/s queues also have these limit distributions. The present analysis differs in that it involves subtle arguments dealing with the convergence of integrals of complex-valued functions. In Section 2 we discuss M/G/1 queues and in Section 3 we discuss GI/M/1 queues.
2. Results for M/G/1 Queues

Property (1.1) encouraged us to investigate the maximum $M_n$ of positive recurrent M/G/1 queues when the arrival rate $\lambda$ and service distribution $G$ vary with $n$ such that the traffic intensity is nearly 1. This is the basis of the following results.

Consider a sequence of positive recurrent M/G/1 queues indexed by $n = 1, 2, \ldots$, where the $n$th process has arrival rate $\lambda_n$ and service distribution $G_n$ with mean $\mu_n^{-1}$. For the $n$th process, let $M_n$ denote the maximum queue length up to the $n$th time the system becomes empty. With no loss in generality, assume that the system is empty at time 0. We shall study the convergence in distribution of $(M_n - a_n)/b_n$ as the traffic intensity $\rho_n = \lambda_n/\mu_n$ tends to 1. Although, our limiting results are for large $\rho_n$, the limits yield good approximations for the distribution of $M_n$ for small as well as large $\rho_n$.

We assume that the Laplace transform

$$\phi_n(z) = \mathbb{E}(e^{zt}G(t))$$

for $z$ complex, is analytic on the region $Re(z) > -\overline{x}_n$, where $-\infty \leq -\overline{x}_n < 0$, and that $\phi_n(x) \to \infty$ for real $x > -\overline{x}_n$. This assumption is equivalent to $\phi_n(x)$ being finite in some real interval $|x| < \varepsilon$ and

$$-\overline{x}_n = \inf \{x \leq 0: \phi_n(x) < \infty\}.$$

One consequence is that all moments of $G_n$ exist. We define

$$\phi_n(z) = \phi_n(\lambda_n (1-z)) - z, \text{ for } Re(z) < 1 + \overline{x}_n/\lambda_n.$$

Lemma 2.2 says that $\phi_n$ has exactly one zero on the real interval $(1, 1+\overline{x}_n/\lambda_n)$. We let $r_n$ denote this zero. Let $G_0$ be another such distribution with $\overline{x}_0, \phi_0$.
and \( r_0 \) defined similarly.

We will show, under some natural conditions, that if \( n(r - 1) \to c \), then \( M_n \) has the limit distribution \( F_c \), where

\[
\begin{align*}
F_0(x) &= \exp(-x^{-1}) \quad \text{when } c = 0 \\
F_c(x) &= \exp[-c/(e^x - 1)] \quad x > 0, \quad \text{when } 0 < c < \infty \\
F_\infty(x) &= \exp(-e^{-x}) \quad \text{when } c = \infty.
\end{align*}
\]

In particular, we will show that

\[
\lim_{n \to \infty} P\left( \frac{M_n - a_n}{b_n} < x \right) = F_c(x) \quad x \in \mathbb{R},
\]

where

\[
\begin{align*}
a_n &= \left\{ \begin{array}{ll}
\alpha_n & \text{if } c = 0 \\
\alpha_n + \beta_n \log n(r_n - 1) & \text{if } c = \infty
\end{array} \right. \\
b_n &= \left\{ \begin{array}{ll}
\beta_n & \text{if } 0 < c < \infty
\end{array} \right.
\end{align*}
\]

and

\[
\alpha_n = \frac{\log[(1-p_n)/\phi'(r_n)]}{\log r_n}, \quad \beta_n = 1/\log r_n.
\]

THEOREM 2.1. Suppose that

\[
\lim_{n \to \infty} G(n/x_n) = G_0(x)
\]

for each \( G_0 \) continuity point, \( r_0 = 1, \lim_{n \to \infty} \alpha_n \neq -\infty \), and when \( n(r_n - 1) \to 0 \)

\[
\lim_{n \to \infty} \frac{(1-\rho_n)}{[n(r_n - 1)(1+\epsilon)]} = 0 \quad \text{for each } \epsilon > 0.
\]

Then the possible limit distributions for \( M_n \) are \( F_c, 0 \leq c \leq \infty \). The \( M_n \) has limit distribution \( F_c \) if and only if \( n(r_n - 1) \to c \). Appropriate norming constants for the convergence (2.2) are given by (2.3).
REMARKS 2.2 (i) The distributions $F_c, 0 \leq c \leq \infty$ are of distinct type: $F_c$ and $F_{c'}$ are of the same type if and only if $c = c'$.

(ii) For any positive recurrent M/G/1 queue, without the artificial dependence on $n$, Theorem 2.1 yields the approximation

\begin{align*}
P(M \log r - \log[(1-\rho)/\phi'(r)] < x) \approx \exp[-n(r-1)/(eX-1)], \ x > 0.
\end{align*}

There are analogous approximations of the distribution of $M_n$ by $F_0$ and $F_\infty$ when $n(r-1)$ is very small or very large. However (2.6) is better since the actual value of $n(r-1)$ appears on the right whereas it doesn't for the $F_0$ and $F_\infty$ approximations, which represent degenerate cases. Furthermore, since $n(r-1)$ appears on the right, (2.6) is accurate when $r$ (or $\rho$) is not near 1. For the M/M/1 queue, we found that the difference between the two sides of (2.6) is below 0.018 when $n \geq 15$ and below 0.01 when $n \geq 20$ for any $\rho$ in $(0,1)$.

(iii) Assumption (2.4) says that $G_n(\lambda_n \lambda_n)$ converges weakly to $G_0$. This implies that $\gamma_n(\lambda_n z) \rightarrow \gamma_0(z)$ and $\phi_n(z) \rightarrow \phi_0(z)$ uniformly on compact sets. We use the latter and $r_0 = 1$ to ensure that: (a) $r_n \rightarrow 1$, and (b) there is an $n > 1$ and $N$ such that $\phi_n(z)$ for $n > N$ has no zeros on the annulus $1 < |z| < n$ other than at $r_n$. Theorem 2.1 is true with (2.4) and $r_0 = 1$ replaced by conditions (a) and (b).

(iv) We use assumption $\lim \alpha_n = -\infty$ along with $r_n \rightarrow 1$ to ensure that $\alpha_n + b x \rightarrow -\infty$. Assumption (2.5) is only for the degenerate case $n(r_n-1) \rightarrow 0$. These two assumptions are automatically satisfied in natural cases such as those in Corollary 2.4.

To prove Theorem 2.1, we use the following properties of $\phi_n$: we suppress the $n$ here for convenience.
LEMMA 2.3. (i) The function $\phi(x)$, for real $x$, is strictly convex on the interval $(0, 1+\overline{x}/\lambda)$ and

$$\phi(x) \to \infty \quad \text{as} \quad x \to 1 + \overline{x}/\lambda.$$  

Furthermore, $\phi(x)$ has exactly two zeros on this interval at 1 and at some $r > 1$.

(ii) The only zeros of $\phi(z)$ on the circles $|z| = 1$ and $|z| = r$ are at 1 and $r$, respectively, and these zeros are of order 1.

(iii) $\phi(z)$ has no zeros on the annulus $1 < |z| < r$.

Proof. (i) The second derivative of $\phi(x)$ exists and is positive, and so $\phi$ is strictly convex. Statement (2.7) is obvious when $\overline{x} < \infty$, and, when $\overline{x} = \infty$, it follows by the strict convexity of $\phi$ and

$$\lim_{x \to 1+\overline{x}/\lambda} \phi'(x) = \lim_{y \to \infty} \int_{0}^{\infty} \text{tye}^{\text{G}(t)} \, dt = 1 = \infty.$$  

Clearly $\phi(1) = 0$ and so the strict convexity and (2.7) ensure that there is exactly one other zero of $\phi$ at some point $r$ in the interval $(1, 1+\overline{x}/\lambda)$.

(ii) Since $\gamma(\lambda(1-x))$ is strictly increasing and convex with fixed points at $x = 1$ and $x = r$ (the zeros of $\phi(x)$), then

$$\gamma(\lambda(1-x)) < 1 \quad \text{when} \quad 0 < x < 1,$$

$$\gamma(\lambda(1-x)) < r \quad \text{when} \quad 0 < x < r.$$  

Then on the circle $|z| = 1$, the only zero of $\phi$ is at 1, since

$$|\phi(z)| \geq |z| - |\gamma(\lambda(1-z))| \geq 1 - \gamma(\lambda(1-\text{Re}z)) > 0 \quad \text{when} \quad z \neq 1 \ (\text{Re}z < 1).$$  

Similarly, on the circle $|z| = r$, the only zero of $\phi$ is at $r$, since

$$|\phi(z)| \geq r - \gamma(\lambda(1-\text{Re}z)) > 0 \quad \text{when} \quad z \neq r \ (\text{Re}z < r).$$  

The zeros of $\phi$ at 1 and $r$ are of order one since $\phi'(1) = 0-1 < 0$, and $\phi'(r) > 0$ by strict convexity.
(iii) By Rouche's theorem and
\[
|\phi(z) - z| = |\gamma(\lambda(1-z))| < \gamma(\lambda(1-|z|)) = \phi(|z|) + |z| < |z| \quad \text{when} \quad 1 < |z| < r,
\]
we know that \(\phi(z)\) and \(z\) have the same number of zeros in \(1 < |z| < r\). Thus \(\phi\) has no zeros there.

Proof of Theorem 2.1. We shall first prove that \(n(r_n - 1) + c\) implies (2.2).
Associated with the \(n\)th \(M/G/1\) process, let \(F_n\) denote the distribution of the maximum queue length in one busy period (the period between two successive entrances to state 0). From Takacs (1965) and Cohen (1969), we know that
\[
(2.9) \quad F_n(m) = 1 - (2\pi i)^{-1} \int_{C_1} (1-z)^{m} \phi_n(z)^{-1} dz/(2\pi i)^{-1} \int_{C_1} z^{m} \phi_n(z)^{-1} dz,
\]
where \(C_1\) is any circle in the \(z\)-plane with center at the origin and with radius less than 1, and the complex integrals are over \(C_1\) in the counter-clockwise direction.

Because the queueing process regenerates each time the system becomes empty, then \(M_n\) is the maximum of \(n\) independent random variables with distribution \(F_n\). Consequently,
\[
P((M_n - a_n)/b_n < x) = F_n(a_n + b_n x)^n.
\]
It is well known that \((1 + \eta_n)^n \to e^\eta\) for any real numbers \(\eta_n\) satisfying \(\eta_n \to \eta\) where \(-\infty < \eta < \infty\). Then to prove (2.2), it suffices to show that
\[
(2.10) \quad \lim_{n \to \infty} n[1 - F_n(a_n + b_n x)] = \begin{cases} 
\frac{1}{x} & \text{when} \quad c = 0 \\
\frac{c}{(e^x-1)} & 0 < c < \infty \\
e^{-x} & c = \infty.
\end{cases}
\]

To this end, consider the integrals in (2.9). We shall express them in a more convenient form. Choose circles \(C_1\) and \(C_n\) in the \(z\)-plane with centers
at the origin and radii less than 1 and greater than $r_n$, respectively, such that $\phi_n$ has no zeros other than 1 and $r$ on the annulus between $C^1_n$ and $C_n$.

This is possible because of the nature of $\phi_n$; see Lemma 2.3. For convenience, we temporarily suppress the subscript $n$ on $\phi_n$, $C^1_n$, $C_n$, $r_n$, $\rho_n$.

From Lemma 2.3, we know that the function $z^{-m}\phi(z)^{-1}$ has poles of order one at 1 and $r$ and is analytic at all other $z$ in the annulus between $C^1$ and $C$.

The residues of this function at these poles are

$$\lim_{z \to 1} (z-1)z^{-m}\phi(z)^{-1} = 1/\phi'(1) = -1/(1-\rho)$$

$$\lim_{z \to r} (z-r)z^{-m}\phi(z)^{-1} = 1/(r\phi'(r)).$$

Then by the residue theorem for complex integration, it follows that

$$(2.11) \quad (2\pi i)^{-1} \int_C z^{-m}\phi(z)^{-1} dz - (2\pi i)^{-1} \int_{C^1} z^{-m}\phi(z)^{-1} dz$$

$$= -1/(1-\rho) + 1/(r\phi'(r)).$$

Similarly,

$$(2.12) \quad (2\pi i)^{-1} \int_C (1-z)z^{-m}\phi(z)^{-1} dz - (2\pi i)^{-1} \int_{C^1} (1-z)z^{-m}\phi(z)^{-1} dz$$

$$= (1-r)/(r\phi'(r)),$$

where the last term is the residue of the integrand of these integrals at $r$; the residue at 1 is 0.

Combining (2.9), (2.11), (2.12) and letting $m_n$ denote the integer $p \cdot t$ of $a_n + b_n x$, we have

$$n[1-F_n(a+b_n x)] = [n(1-r)/(r\phi'(r)) - n(2\pi i)^{-1} \int_C (1-z)z^{-m}\phi(z)^{-1} dz]$$

$$/[1/(1-\rho) + r\phi'(r)^{-1} - (2\pi i)^{-1} \int_C z^{-m}\phi(z)^{-1} dz].$$
That is,
\[(2.13)\quad \phi_n[1-F(a + b x)] = (1+\delta_n)/[\phi_n[n(r_n-1)] + \varepsilon_n] \]

where, returning the subscript \(n\) to \(\phi_n, r_n, \phi_n, c_n,\)

\[
\zeta_n = \frac{\phi_n}{n(r_n-1)}/(1-\rho_n) \\
\delta_n = \zeta_n(1-\rho_n)[n(r_n-1)]^{-1}(2\pi)^{-1}\int_{C_n} (1-z)^{-m} n_{\phi_n}(z)^{-1}dz \\
\varepsilon_n = \zeta_n(1-\rho_n)[n(r_n-1)]^{-1}(2\pi)^{-1}\int_{C_n} z^{m} n_{\phi_n}(z)^{-1}dz.
\]

We first note that \(n(r_n-1) \to c\) implies
\[(2.14)\quad \lim_{n \to \infty} \phi_n[n(r_n-1)] = \begin{cases} \exp(x) & c = 0 \\
\exp(c) & 0 < c < \infty \end{cases} \]

This follows since
\[(2.15)\quad \zeta_n = \exp[a + b x + o(1)] \log r_n - x/\varepsilon_n \]

\[
\begin{cases} 
1 + x n(r_n-1) + o(1) & c = 0 \\
1 + x + o(1) & 0 < c < \infty \\
n(r_n-1)e^{x+o(1)} & c = \infty.
\end{cases}
\]

For case \(c = 0\), use \(e^u = 1 + u + o(u)\) as \(u \to 0\) and \((v - 1)^{-1}\log v - 1\) as \(v \to 1\).

We now show that \(\zeta_n\) and \(\varepsilon_n\) converge to 0. Choose \(\eta\) in the interval \((1, 1+\varepsilon_0)\) such that \(\phi_n\) has no zeros on the annulus \(1 < |z| < \eta\). This is possible due to the nature of \(\phi_n\). Since \(\phi_n(z) \to \phi_0(z)\) uniformly on compact sets, there is a positive integer \(N\) such that \(\phi_n(z)\), for \(n \geq N\), has no zeros on \(1 < |z| < \eta\) other than at \(r_n\). Therefore, we can take each \(C_n\), for \(n \geq N\),

to be the circle with radius \(r\). Letting \(B_n = \sup \phi_n(z)^{-1}: |z| = \eta\) and
using (2.15) we have

\[ |\delta_n| < \zeta_n (1-\rho_n)[n(r_n-1)]^{-1}(2\pi)^{-1} \int_{|z|=1} |1-z| |z|^{-n|\phi_n(z)|^{-1}}dz \]

\[ \leq \begin{cases} 
0(1)B_n (1-\rho_n)/[n(r_n-1)\eta_n] & c = 0 \\
0(1)B_n (1-\rho_n)/\eta_n & 0 < c < \infty. 
\end{cases} \]

Applying $B_n + B_0 < \infty$, assumption (2.5), and $m_n \to \infty$ to these expressions, it follows that $\delta_n \to 0$. A similar argument yields $\varepsilon_n \to 0$.

Using these limit statements for $\zeta_n$, $\delta_n$ and $\varepsilon_n$ in (2.13) implies (2.10), which in turn yields (2.2). Thus, we have shown that $n(r_n-1) \to c$ implies (2.2).

To prove the converse, suppose $M_n$ has the limit distribution $F_c$. Let $n'(r_n-1)$ be any convergent subsequence of $n(r_n-1)$ on the compact set $[0,\infty]$ and let $c' = \lim n'(r_n-1)$. Then, from what we just proved, $M_n$, has the limit distribution $F_{c'}$. But $M_{n'}$, as a subsequence of $M_n$, also has the limit distribution $F_{c'}$. Then by Khinchine's Theorem (see for instance Theorem 1.2.3 of Leadbetter et al. (1983)), the distributions $F_{c'}$ and $F_c$ are of the same type. Consequently $c' = c$. Thus, any convergent subsequence of $n(r_n-1)$ must converge to $c$, and hence $n(r_n-1) \to c$. A similar argument shows that $F_c$, $0 < c < \infty$, are the only possible limit distributions of $M_n$.

Two examples of Theorem 2.1 are as follows.

**COROLLARY 2.4.** The assertions of Theorem 2.1 are true under the single hypothesis $\rho_n \to 1$ when (i) the service times are constant or (ii) each $G_n$ is a gamma distribution with scale parameter $\eta_n$ and order $k$.

**Proof.** It suffices to verify the hypotheses of Theorem 2.1 for the two cases.

First, suppose the service times are constant. Then $\gamma_n(z) = \exp(-z/\mu_n)$ and
\( \phi_n(z) = \exp[-\rho_n (1-z)]-z \) for each complex \( z \) (\( \overline{x_n} = \infty \)). The zero \( r_n \) of \( \phi_n \) on \((1, \infty)\) is given by \((r_n-1)^{-1}\log r_n = \rho_n \). Assumption (2.4) is satisfied since \( \rho_n + 1 \) implies that \( \gamma_n(\lambda z) = \exp(-\rho_n z) + \gamma_0(z) = \exp(-z) \). Clearly \( r_n + r_0 = 1 \).

Now, using \( \phi'_n(z) = \rho_n (\phi_n(z) + z) - 1 \) and \( \phi'_n(r_n) = \rho_n r_n - 1 \), we can write

\[
\alpha_n = \frac{\log[(r_n-1) - \log r_n] - \log[r_n \log r_n - (r_n-1)]}{\log r_n}.
\]

Then by four applications of L'Hopital's rule and \( r_n + 1 \), it follows that \( \alpha_n \approx -1 \). Also, assumption (2.5) is satisfied, since an application of L'Hopital's rule gives

\[
(1-\rho_n)/(r_n-1) = [(r_n-1) - \log r_n]/(r_n-1)^2 + 1/2.
\]

Next, assume that \( G \) is a gamma distribution with Laplace transform

\[
\gamma_n(z) = (1 + \eta^{-1} n z)^{-k}, \quad \text{Rez} \geq \overline{x_n} = -\eta_n.
\]

Then \( \phi_n(z) = [1+(\rho_n/k)(1-z)]^{-k} - z \), \( \text{Rez} < 1 + \eta_n / \lambda_n \), and its zero \( r_n \) is one of the \( k+1 \) solutions of \( 1-r_n [1-(\lambda_n / \eta_n) r_n^{-1}] = 0 \). Assumption (2.4) is satisfied since \( \rho_n = k\lambda_n / \eta_n + 1 \) implies that \( \gamma_n(\lambda z) + \gamma_0(z) = (1+k^{-1} z)^{-k} \). Clearly \( r_n \to r_0 \) and \( r_0 = 1 \) since \( \phi'_0(1) = \rho_0 - 1 = 0 \). Using

\[
\phi'_n(z) = \rho_n (\phi_n(z)+z)/[1 + \rho_n/k(1-z)] - 1 \quad \text{and} \quad \phi'_n(r_n) = \rho_n r_n^{1+k^{-1}} - 1,
\]

we can write

\[
\alpha_n = \frac{\log[(r_n-1) - k(1-r^{-1/k})] - \log[k(r_n^{1+k} - r) - (r-1)]}{\log r_n}.
\]

From five applications of L'Hopital's rule, it follows that \( \alpha_n \approx -1 \). Finally, assumption (2.5) is satisfied since an application of L'Hopital's rule gives

\[
(1-\rho_n)/(r_n-1) = [(r_n-1) - k(1-r_n^{-1/k})] / (r_n-1)^2 + (1+k)/2.
\]
3. Results for GI/M/1 Queues

In this section, we show that the limiting behavior of extreme values of GI/M/1 queues is analogous to that for M/G/1 queues. Consider a sequence of positive recurrent GI/M/1 queueing systems indexed by \( n \neq 1, 2, \ldots \). For the \( n \)th system, let \( G_n \) denote the distribution of the times between arrivals and let \( \mu_n^{-1} \) denote the mean of the exponential service times. Assuming the system is empty at time 0, let \( M_n \) denote the maximum queue length up to the \( n \)th time the system becomes empty.

Suppose that the Laplace transform \( \gamma_n(z) \) of \( G_n \) has the same form as in Section 2, and let

\[
\psi_n(z) = \gamma_n(\mu_n (1 - z)) - z \quad \text{for } \Re z < 1 + \frac{x_n}{\mu_n}.
\]

An easy check shows that \( \psi_n \) has the same properties as \( \phi_n \) in Lemma 2.2 with \( \mu_n \) in place of \( \lambda_n \) and \( r_n \) and 1 reversed. In particular, \( \psi_n(x) \) has exactly two zeros on \((0, 1+x_n/\mu_n)\) at 1 and at some \( r_n < 1 \), and \( \psi_n(z) \) has no zeros in the annulus \( r_n < |z| < 1 \).

For the following result, we use the notation in (2.2) and (2.3) with \( n(r_n-1) \) replaced by \( n(1-\rho_n) \) and

\[
\alpha_n = \beta \log\left[\frac{-(1-\rho_n)\psi_n(r_n)}{\psi_n(r_n)}\right] \quad \beta_n = -1 / \log r_n.
\]

THEOREM 3.1. Suppose \( G_n(\cdot/\mu_n) \) converges weakly to \( G_0 \) with \( r_0 = 1 \), and \( \lim_{n \to \infty} \alpha_n \neq \infty \).

Then the possible limit distributions for \( M_n \) are \( F_c \), \( 0 \leq c \leq \infty \). The \( M_n \) has limit distribution \( F_c \) if and only if \( n(1-\rho_n) - c \). Appropriate norming constants for the convergence (2.2) are given by (2.3) and (3.1).

Proof. This follows by a proof paralleling that of Theorem 2.1. Here the maximum queue length in a busy cycle has the distribution...
\begin{equation}
1 - F_n(m) = 2\pi i \int_C z^{-m} \Phi_n(z)^{-1} dz \quad m = 0, 1, \ldots,
\end{equation}

where \( C \) is a circle in the \( z \)-plane with center at the origin and radius less than \( r_n \); see Cohen (1969). Choose circles \( C_n^1 \) and \( C_n \) in the \( z \)-plane with centers at the origin and radii less than \( r_n \) and greater than 1, respectively, such that \( \psi_n(z) \) has no zeros other than \( r_n \) and 1 on the annulus between \( C_n^1 \) and \( C_n \). Then by the residue theorem

\begin{align*}
(2\pi i)^{-1} \int_{C_n^1} z^{-m} \psi_n(z)^{-1} dz - (2\pi i)^{-1} \int_{C_n} z^{-m} \psi_n(z)^{-1} dz &= \psi_n'(1)^{-1} + r_n^{-m} \psi_n'(r_n)^{-1}.
\end{align*}

Using this, (3.2) and \( \psi_n'(1)^{-1} = \rho_n^{-1} - 1 \), we have

\begin{equation}
n[1 - F_n(a_n b_n x)] = \frac{\zeta_n - \rho_n}{n(1 - \rho_n)} + \epsilon_n \approx \frac{1}{n(1 - \rho_n)},
\end{equation}

where

\begin{align*}
\zeta_n &= r_n^{-m} (1 - \rho_n) / \psi_n'(r_n), \\
\epsilon_n &= (2\pi i n)^{-1} \int_{C_n} z^{-m} \psi_n(z)^{-1} dz
\end{align*}

and \( m_n \) is the integer part of \( a_n b_n x \). Arguing as in the proof of Theorem 2.1, one can show that \( n(1 - \rho_n) \to c \) implies (2.10) and hence (2.2). The rest of the proof is the same as before.

\textbf{REMARKS 3.2.} Analogues of Remarks 2.2 and Corollary 2.4 apply to Theorem 3.1. Note that since (3.3) is simpler than (2.13), Theorem 3.1 does not need an assumption like (2.5).

\textbf{4. Acknowledgement}

I am grateful to Professor W. Cohen for his helpful comments on this work.
