Abstract

A composite grid was generated in an attempt to improve grid quality for a typical turbine blade with large camber in terms of mesh control, smoothness, and orthogonality. This composite grid consists of the C-grid and O-grids in the immediate vicinity of the blade and the H-grid in the upstream region and in the middle of the blade passage between the C-grids. It provides a good boundary layer resolution around the leading-edge region for viscous calculation, has orthogonality at the blade surface and slope continuity at the C-H interface, and has flexibility in controlling the mesh distribution in the upstream region without using excessive grid points. This composite grid eliminates the undesirable qualities of a single grid when generated for a typical turbine geometry.

A finite-volume lower-upper (LU) implicit scheme can be used in solving for the turbine flows on the composite grid. This grid has a special grid node that is connected to more than four neighboring nodes in two dimensions and to more than six nodes in three dimensions. But the finite-volume approach poses no problem at the special point because each interior cell has only four neighboring cells in two dimensions and only six cells in three dimensions. The finite-volume LU-implicit scheme was demonstrated to be robust and efficient for both external and internal flows in a broad flow regime.

Introduction

Turbine blades are often designed to have substantial thickness and camber and rounded leading and trailing edges. For a typical turbine blade, the H-grid does not provide a good boundary layer resolution around the leading edge. If very fine meshes are used to resolve this, the number of grid points in the upstream region becomes excessive. Thus mesh points would be wasted. A turbine flow analysis on an H-grid indicated that the standard H-grid needs cusps on the leading and trailing edges to reduce the numerical errors around those edges. The H-grid has large grid skewness and slope discontinuity, which causes somewhat large numerical errors around leading edges. If a C-grid were used, it would provide a better resolution around the leading edge. A standard C-grid was generated for a core turbine stator vane. It reveals large grid skewing on the suction side of the flow passage, which should increase numerical errors.

For a typical turbine blade, no single grid offers satisfactory grid properties in the entire turbine stator or rotor passage.

A two-dimensional O/H patched grid used in a turbine cascade computation shows the slope discontinuity at the O/H grid interface and has extremely large-aspect-ratio meshes near the leading edge. The numerical scheme used in that work is a cell-centered scheme based on the Beam and Warming approximate factorization. Although the flexibility of the scheme is indicated in two dimensions, its likely limitations in three dimensions suggest an alternative approach.

Two- and three-dimensional composite grids were generated in an attempt to improve the grid quality in terms of mesh control, smoothness, and orthogonality. A numerical scheme that will run on this composite grid is discussed.

Composite Grid

A stator vane ring and the vane geometry at mean section are shown in Figs. 1(a) and (b), respectively. This vane ring was used for an annular cascade experiment reported in Ref. 2. To alleviate numerical errors associated with the H-grid skewness for the blunt leading edge, a standard C-grid (Fig. 2(a)) was generated to examine any possible advantage over the H-grid for this turbine vane geometry. But the grid became very skewed on the suction side of the passage because the blade was highly cambered (Fig. 2(b)). In addition, the control of the mesh distribution in the blade region was limited with the C-grid, because it affected the mesh distribution in the upstream region. Results of numerical simulations
Two- and three-dimensional composite grids were generated as shown in Figs. 3(a) and (b), respectively. The blades had a constant profile from hub to tip and were stacked at the trailing edge (Fig. 3(c)). Only a selected number of grid lines are shown for illustration. This composite grid consists of the C-grid (or O-grid) in the immediate vicinity of the blades and the H-grid in the upstream region and in the middle of the blade passage between the C-grids. The C-grid (or O-grid) can be generated by using either the elliptic grid method or the algebraic method. At the C-grid and H-grid interface (or O-H interface) the slope continuity was preserved so that no special numerical approximations are needed for the derivatives at the interface. The C-grid (or O-grid) is orthogonal to the blade surface and provides a good boundary layer resolution near the leading edge. This composite grid has better smoothness and orthogonality and provides more flexibility in controlling the meshes than any single grid for a typical turbine blade with large camber and a rounded leading edge.

The C-grid portion of the composite grid was generated by the elliptic grid generation code. Two subroutines of the code were modified. The outer boundary subroutine was modified, to improve generation of the periodic boundaries, by using the mean camber line for high-solidity blade rows. The inner boundary subroutine was modified to allow a more general clustering of points about the leading and trailing edges of highly cambered turbine blades. Figure 4 illustrates the portion of the C-grid between \( n = 0 \) and \( n = n_C \) that was retained for the composite grid. The grid lines at \( n = 0 \) and \( n = n_{max} \) are inner and outer boundaries, respectively. The choice of \( n_C \) is arbitrary and may depend on the extent of the shear flow region. The \( n^r \) coordinate is a translation of the \( n \) coordinate by one pitch in circumferential direction. For the H-grid in the middle between the blades, the C-grid points at \( n = n_C \) and \( n = n_{C+1} \) on the suction side and at \( n^r = n_C^r \) and \( n^r = n_{C+1}^r \) on the pressure side are used in the cubic spline to preserve slope continuity at the C-H interface and to effect a smooth change in mesh size. The three-dimensional grid in Fig. 3(b) was constructed algebraically from the composite grids of the hub and shroud surfaces by using the cubic spline and exponential stretching.

A two-dimensional composite grid was also generated for the first-stage stator and rotor of the space shuttle main engine (SSME) fuel turbopump turbine. Figure 5 shows the construction of the C-H composite grid for the rotor blade. Figure 6 shows the composite grid generated for the stator vane. One merit of the composite grid is the flexibility in constructing the H grid in the upstream region. One can choose the number and distribution of meshes, and the H grid can be extended in the upstream direction independently of the C grid part of the composite grid around the blade. With this flexibility the downstream end of the grid for the stator can be easily matched with the upstream end of the grid for the rotor in the wakeless space between the stator and rotor. Figure 7 illustrates that the composite grid can be easily constructed for a stator/rotor interaction study.

### Numerical Scheme

**Semidiscrete Finite-Volume Scheme**

The two-dimensional C-H composite grid has an unusual grid point that is connected to more than four neighboring nodes (Fig. 8(a)). At this point the usual differencing techniques cannot be applied. If a standard finite-difference scheme were used to solve a flow problem on this composite grid, it would be difficult to treat this special point. A finite-volume scheme to be used with this composite grid presents no problem and requires no special treatment because each interior cell of this composite grid has only four neighboring cells in two dimensions and six neighboring cells in three dimensions (Fig. 8(b)). The finite-volume scheme is described briefly here.

The Euler equations in integral form can be written as

$$\frac{d}{dt} \int_{\Omega} w \, d\Omega + \int_{\partial \Omega} F \cdot dS = 0$$

for a fixed region \( \Omega \) with boundary \( \partial \Omega \). Here \( w \) represents the conserved quantity, \( F \) is the corresponding flux term, and \( t \) is time.

A convenient way to ensure a steady state solution independent of the time step is to separate the space and time discretization procedures. In the semidiscrete finite-volume scheme one begins by applying a semidiscretization in which only the spatial derivatives are approximated. To derive a semidiscretized model that can be used to treat complex geometric domains, the computational domain is divided into quadrilateral cells. Assuming that the dependent variables are known at the center of each cell, a system of ordinary differential equations is obtained by applying equation (1) separately to each cell. These equations have the form

$$\frac{d}{dt} \left( S_{ij} \mathbf{w}_{ij} \right) + Q_{ij} = 0$$

where \( S_{ij} \) is the cell area and \( Q_{ij} \) is the net flux out of the cell. This can be evaluated as

$$\sum_{k=1}^{4} \left( \Delta x_k f_k - \Delta y_k g_k \right)$$

where \( f_k \) and \( g_k \) denote values of the flux vectors \( f \) and \( g \) on the \( k \)th edge, \( \Delta x_k \) and \( \Delta y_k \) are the increments of \( x \) and \( y \) along the edge with appropriate signs, and the sum is over the four sides of the cell. The flux vectors are evaluated, for example, by averaging the values in the cells on either side of the edge:

$$f_1 = \frac{1}{2} \left( f_{1+1,1} + f_{1,1} \right)$$

The scheme constructed in this manner reduces to a central difference scheme on a Cartesian grid and is second order accurate in space provided that the mesh is smooth enough. It also has the property that uniform flow is an exact solution of the difference equations.

**LU Implicit Scheme**

The composite grid is generated to be used for both inviscid and viscous flow calculations. For
viscous calculations the C- or O-meshes must be very fine to resolve the boundary layer. And it is likely that the time step imposed by an explicit scheme is too small to resolve the boundary layer. A second implicit scheme is required to have a faster convergence. Although the alternating direction implicit (ADI) scheme has been valuable in two-dimensional problems, its inherent limitations in three dimensions suggest an alternative approach. An LU implicit scheme was demonstrated to be efficient and robust for both external and internal flows in a broad flow regime.1-14 The scheme was extended for three-dimensional flows on an H-grid.15 This scheme will be used for the numerical simulation of turbine flows on the composite grid.

The conservation law form of the Euler equations in Cartesian coordinates for two-dimensional flow is

\[ \frac{\partial \mathbf{w}}{\partial t} + \nabla \cdot \mathbf{F} = 0 \]

where \( \mathbf{w} \) is the vector of dependent variables and \( \mathbf{F} \) are convective flux vectors:

\[ \mathbf{F} = \left[ \rho \mathbf{u}, \rho \mathbf{u}^2 + p, \rho \mathbf{u} \mathbf{v} \right]^T \]

where \( \rho, u, v, E, \) and \( p \) are density, velocity components, total energy, and pressure. The pressure is obtained from the equation of state

\[ P = \rho \gamma (\gamma - 1) \left[ E - \frac{1}{2} (u^2 + v^2) \right] \]

where \( \gamma \) is the ratio of specific heats. These equations are to be solved for a steady state \( \partial \mathbf{w} / \partial t = 0 \), where \( t \) denotes time.

Let the Jacobian matrices be

\[ A = \frac{\partial \mathbf{F}}{\partial \mathbf{w}}, \quad B = \frac{\partial \mathbf{A}}{\partial \mathbf{w}} \]

and let the correction be

\[ \mathbf{w}^{n+1} = \mathbf{w}^n + \delta \mathbf{w} \]

where \( n \) denotes the time level.

The linearized implicit scheme for a system of nonlinear hyperbolic equations such as the Euler equations can be formulated as

\[ \left[ I + B \right] \delta \mathbf{w} + \mathbf{R} = 0 \]

where \( I \) is the identity matrix and \( \mathbf{R} \) is the residual

\[ \mathbf{R} = D_x F^{(n)} + D_y G^{(n)} \]

Here \( D_x \) and \( D_y \) are central difference operators that approximate \( \partial \mathbf{F} / \partial x \) and \( \partial \mathbf{F} / \partial y \).

If \( \delta \mathbf{w} = 1/2 \), the scheme remains second order accurate in time; for other values of \( \delta \) the time accuracy drops to first order. The unfactored implicit scheme (eq. (7)) produces a large block-banded matrix, which is very costly to invert and requires huge storage. An unconditionally stable implicit scheme that has error terms at most of order \( \delta t \). In any number of space dimensions can be derived by LU factorization

\[ \left[ I + B \delta t (D_x A^+ + D_y B^+) \right] \left[ I + B \delta t (D_x A^- + D_y B^-) \right] \]

\[ \delta \mathbf{w} + \mathbf{R} = 0 \]

where \( D_x^+ \) and \( D_x^- \) are backward difference operators placed in the lower and upper factors. The reason for splitting is to ensure the diagonal dominance of lower and upper factors as well as to make use of the built-in implicit dissipation.

Here \( A^+, A^-, B^+, \) and \( B^- \) are constructed so that the eigenvalues of \( "+" \) matrices are nonnegative and those of \( "-" \) matrices are nonpositive.

This composite grid, which has a C-type (or O-type) grid in the immediate vicinity of the turbine blade, provides a good boundary layer resolution around the leading-edge region for viscous calculation, has orthogonality at the blade surface and slope continuity at the C-H (or O-H) interface, and controls the mesh distribution in the upstream region without using excessive grid points. This composite grid eliminates the undesirable qualities of a single grid when generated for a typical turbine geometry.

Concluding Remarks

Two- and three-dimensional composite grids were generated to improve grid quality for an annular turbine cascade in terms of smoothness, resolution, and orthogonality. This composite grid, which has a C type (or O type) grid in the immediate vicinity of the turbine blade, provides a good boundary layer resolution around the leading-edge region for viscous calculation, has orthogonality at the blade surface and slope continuity at the C-H (or O-H) interface, and controls the mesh distribution in the upstream region without using excessive grid points. This composite grid eliminates the undesirable qualities of a single grid when generated for a typical turbine geometry.

The C-H composite grid has flexibility in constructing the H-grid in the upstream region so that the grids for the stator vanes and rotor blades of the SSME fuel turbopump turbine can easily be matched in the vanesless space and can be used for the stator-rotor interaction study.

A finite volume lower upper (LU) implicit scheme is to be used in solving the turbine flows on the composite grid. This grid has a special grid node that is connected to more than four neighboring nodes in two dimensions and to more than six nodes in three dimensions. But the finite volume approach poses no problem at the special point because each interior cell has only four neighboring cells in two dimensions and only
six cells in three dimensions. The finite-volume
LU implicit scheme was proven to be robust and
efficient in a broad flow regime and is expected
to yield accurate solutions on the improved compos-
ite grid.
