**Abstract:**

A one-dimensional large-signal analysis computer code for Helix traveling-wave tubes was developed. The program is based on the theory developed by J.E. Rowe and M.K. Scherba. The program was written in FORTRAN 77 and implemented on an HP-1000 computer at Teledyne MEC in Palo Alto CA. The program is well documented and can accommodate attenuators, severs, velocity changes, linear velocity tapers, and multiple input signals.

Two Teledyne MEC tubes were simulated with the program and the results were in very good agreement with experimental data.
Block 16. Supplementary Notation (Cont'd)
requirements of the degree of Electrical Engineer.
ACKNOWLEDGMENTS

This work was pursued under the joint sponsorship of the United States Air Force and Teledyne MEC in conjunction with the University of Utah under the Air Force Thermionic Engineering and Research (AFTER) Program. The author wishes to thank Professors Richard W. Grow and J. Mark Baird at the University of Utah for their suggestions and guidance. Thanks are also due to several people in the Advanced Development Group at Teledyne MEC. Phil Lally, Larry Wood, and Eric Nettesheim provided helpful discussions about large-signal theory. Keith Winnovich and Lou Lau supplied the experimental data used to evaluate the program. The work described in this report is heavily dependent upon the work of Rick Baer while he was at Teledyne MEC. Finally, a special thanks goes to Dr. Brian Boe for his assistance and encouragement throughout the course of the project.

I. INTRODUCTION

Large-signal analysis programs are widely used by the microwave tube community to predict the performance of helix traveling-wave tubes. These nonlinear programs allow an engineer to optimize a tube design without building several prototype tubes. Unfortunately, currently available programs are complex and poorly documented. The purpose of this project is to provide a structured, well documented large-signal analysis program to the scientific and industrial community.

The program, TWT1D, is based on the one-dimension nonlinear theory developed by M. K. Scherba and J. E. Rowe. The program was written in FORTRAN77 and implemented on an HP-1000 computer at Teledyne MEC in Palo Alto, California. Complete documentation for the program, including a source code listing and a User's Manual, is given in this report.
II. LARGE-SIGNAL THEORY

The large-signal theory of traveling-wave amplifiers differs from small-signal theory in several ways. Perhaps the most significant difference is the way each theory models the electron beam. In small-signal theory, the beam is modeled as drifting charged fluid. Its charge density and electron velocity are single valued functions of distance, and electrons cannot overtake one another. This treatment of the electron beam is called an Eulerian formulation. By comparison, the Lagrangian analysis used in large-signal theory breaks the beam up into representative charge groups. This approach allows charge density and electron velocity to be multivalued functions, and electrons to overtake one another. Another difference between the theories is the way they treat the force and continuity equations. The equations are linearized in small-signal theory, so the theory is limited to circuits with small $c$ and small input signals. Linearizing the equations allows them to be solved analytically. The solution is a single number which gives the gain/unit length for the tube. By contrast, the large-signal theories have no analytic solution and must be solved on a computer. The resulting solution is a profile of power versus axial position.

The large-signal theory offers many advantages over small-signal theory. Since the equations are nonlinear, harmonics can be generated and followed down the tube. This allows the effects of intermodulation to be studied. Unlike small-signal theory, large-signal theory can be used to predict the saturation power and efficiency of a tube. In addition, using a Lagrangian analysis means that electron trajectories...
can be followed down the tube so beam bunching can be observed. Finally, the theory can accommodate attenuators, severs, and velocity changes.

The first attempt at developing a large-signal theory for helix traveling-wave tubes was made by A. T. Nordsieck in 1953. He was the first to use Lagrangian analysis to model the interaction between the circuit and the electron beam for a single input signal. However, his theory was subject to several limitations. To begin with, he assumed that space-charge forces could be neglected. Secondly, he limited his theory to lossless circuits with small $C$. A year later, H. C. Poulter extended the theory to include space-charge forces and to account for circuit loss and finite $C$. Two years after that, J. E. Rowe amended the theory to allow for circuits with a large $C$. Finally, in 1971, M. K. Scherba and J. E. Rowe expanded the theory to include multiple input signals. It is this theory that is the basis for the program TWTID.

In Rowe's model, the helix is represented by a lumped element transmission line, and the electron beam is represented by disks of charge. These charge groups move along the circuit inducing charges in the circuit. The RF field in the circuit interacts with the electron disks and causes them to bunch. This model was first used by Brillouin, and is schematically represented in Fig. 1.
Fig. 1. Schematic model of a helix with an electron beam.

where

\[ d_0 = \text{length of section} \]
\[ R_0 = R d_0 = \text{resistance/section} \]
\[ L_0 = L d_0 = \text{inductance/section} \]
\[ C_0 = C d_0 = \text{capacitance/section} \]
\[ I_n = \text{current in } L_0 \text{ of section } n \]
\[ V_n = \text{potential on capacitor } n \]
\[ Q_n = C_0 V_n = \text{charge on capacitor } n \]
\[ q'_n = \rho_n d_0 = \text{charge in the beam in section } n \]

The circuit equation for this transmission line is

\[
\frac{\partial^2 V}{\partial t^2} + \frac{R}{L} \frac{\partial V}{\partial t} - \frac{2}{v_0} \frac{\partial^2 V}{\partial z^2} = v_0^2 Z_0 \left( \frac{\partial^2 \rho}{\partial t^2} + \frac{R}{L} \frac{\partial \rho}{\partial t} \right)
\]

where the following definitions have been used:
$v_0 \Delta \sqrt{1/LC} = \text{the characteristic phase velocity of the circuit}$

$Z_0 \Delta \sqrt{L/C} = \text{the characteristic impedance of the circuit}$

To express this equation in Pierce\textsuperscript{6} notation, the following relation is used:

$$R/L = 2\omega Cd$$  \hspace{1cm} (2)$$

where $C$ is Pierce's gain parameter and $d$ is his loss parameter. The equation then becomes

$$\frac{\partial^2 V}{\partial t^2} - \frac{v_0^2}{2} \frac{\partial^2 V}{\partial z^2} + 2\omega Cd \frac{\partial V}{\partial t} = v_0 Z_0 \left( \frac{\partial^2 \rho}{\partial t^2} + 2\omega Cd \frac{\partial \rho}{\partial t} \right)$$  \hspace{1cm} (3)$$

For multiple signals, there will be a circuit equation for each signal:

$$\frac{\partial^2 V_n}{\partial t^2} - \frac{v_0^2}{2} \frac{\partial^2 V_n}{\partial z^2} + 2\omega C_n d_n \frac{\partial V_n}{\partial t} = v_0 Z_0 \left( \frac{\partial^2 \rho_n}{\partial t^2} + 2\omega C_n d_n \frac{\partial \rho_n}{\partial t} \right)$$  \hspace{1cm} (4)$$

A. Phase Relation Equation

In his Lagrangian analysis, Nordsieck introduced two independent variables. They are the normalized distance, $y$, and the entry phase of the fundamental component of the input signal, $\phi_{01}$. They are defined as

$$y \Delta \frac{C \omega_1}{u_0} \frac{z}{z}$$  \hspace{1cm} (5)$$

$$\phi_{01} \Delta \frac{\omega_1 z}{u_0} = -\omega_1 t_0$$  \hspace{1cm} (6)$$
where \( \omega_1 \) is the fundamental frequency in the radians, and \( C_1 \) is the gain parameter for the fundamental frequency. \( u_0 \) is the dc stream velocity in m/s, and \( z \) is the axial position on the tube measured in meters.

Using these new variables, the circuit equation becomes

\[
\frac{\partial^2 v_n(y,t)}{\partial t^2} - C_1^2 \frac{1}{\omega_1} \left( \frac{v_0}{u_0} \right)^2 \frac{\partial^2 v_n(y,t)}{\partial y^2} + 2 \omega_n C_n \frac{\partial v_n(y,t)}{\partial t} = \frac{v_0}{u_0} \left( \frac{\partial^2 \rho_n(y,t)}{\partial t^2} + 2 \omega_n C_n \frac{\partial \rho_n(y,t)}{\partial t} \right)
\]

(7)

Nordsieck also introduced the following dependent variables:

\[
\phi_n(y, \theta_{01}) = \omega_n \left( \frac{z}{u_0} - t \right) - \theta_n(y) = \frac{\omega_n}{\omega_1 C_1} y - \omega_n t - \theta_n(y)
\]

(8)

\[
u_z = \frac{dz}{dt}_{t, z_0} = \frac{u_0}{C_1 \omega_1} \frac{dy}{dt} = u_0 \left[ 1 + 2C_1 u(y, \theta_{01}) \right]
\]

(9)

where \( \phi_n \) is the instantaneous charge group phase in radians, and \( \theta_n \) is the phase lag in radians of the circuit wave relative to a traveling wave with phase velocity \( u_0 \). This phase lag is due to beam loading as the wave gets energy from the beam. \( u_z \) is the electron velocity normalized to the initial average electron velocity, \( u_0 \). Taking the derivative with respect to time of Eq. 8 and substituting Eq. 9 yields

\[
\frac{\partial \phi_n(y)}{\partial y} + \frac{\partial \phi_n(y, \theta_{01})}{\partial y} = \frac{\omega_n}{\omega_1 C_1} \left[ 1 - \frac{1}{1 + 2C_1 u(y, \theta_{01})} \right]
\]

(10)

This is the first of Rowe's large-signal equations. It is the velocity-phase equation relating \( u_z \), \( \theta_n \), and \( \phi_n \).
B. Circuit Wave Equations

The next two large-signal equations arise from the circuit equation. To evaluate the circuit equation, define the RF voltage,

\[ V_n(y, \phi_n) = \sum_n V(y) V(\phi_n) \]  

(11)

where

\[ V(y) = \frac{Z_{01} I_0}{C_1} A_n(y) \text{ and } V(\phi_n) = e^{-j\phi_n} \]  

(12)

\( Z_{01} \) is the interaction impedance for the fundamental frequency, and \( A_n(y) \) is the normalized circuit voltage amplitude for the \( n \)th frequency. Substituting the derivatives of Eq. 11 into Eq. 4 yields an equation in terms of \( \sin \phi_n \) and \( \cos \phi_n \). Since these terms are mutually orthogonal, they can be separated and the original circuit equation can be expressed as two equations,

\[
\frac{d^2 A_n(y)}{dy^2} - A_n(y) \left[ \left( \frac{\omega_n}{\omega_1} - \frac{d\phi_n}{dy} \right)^2 \left( \frac{1 + C_n b_n}{C_1} \right)^2 \right] = -\frac{R_n \cos (\rho)}{\omega_1 C_1 Z_{01} I_0} \left( \frac{u_0}{v_{0n}} \right)^2 
\]

(13)

\[
A_n(y) \left[ \frac{d^2 \phi_n}{dy^2} - 2 C_n \frac{d}{dy} \left( \frac{\omega_n}{\omega_1} \right)^2 \left( \frac{1 + C_n b_n}{C_1} \right)^2 \right] - 2 \frac{dA_n(y)}{dy} \left( \frac{\omega_n}{\omega_1} \right) \left( \frac{d\phi_n}{dy} \right) = -\frac{R_n \sin (\rho)}{\omega_1^2 C_1 Z_{01} I_0} \left( \frac{u_0}{v_{0n}} \right)^2 
\]

(14)
where $R_n \sin (p)$ and $R_n \cos (p)$ are the sine and cosine parts of the space-charge expression, and $b_n$ is Pierce's velocity parameter. Now the problem remains of expressing the space-charge expression in terms of $\sin \phi_n$ and $\cos \phi_n$. Since the beam-charge density is rich in harmonics, it is convenient to expand it into a Fourier series:

$$
\rho_n(y, \phi_n) = \sum_{m=1}^{\infty} \left[ \frac{\sin m\phi_n}{\pi} \int_0^{2\pi} \rho \sin m\phi_n d\phi_n \right] + \int_{m=1}^{\infty} \left[ \frac{\cos m\phi_n}{\pi} \int_0^{2\pi} \rho \cos m\phi_n d\phi_n \right]
$$

(15)

The $\rho$ inside the integral may be determined from continuity arguments:

$$
\rho = \frac{I_0}{u_0} \left| \frac{\partial \phi_{01}}{\partial n} \right| \left| \frac{1}{1 + 2C_1 u(y, \phi_{01})} \right|
$$

(16)

Using this expression inside the Fourier integral yields

$$
\rho_n(y, \phi_{0n}) = \frac{I_0}{u_0} \sum_m \left[ \sin m\phi_n \int_0^{2\pi} \frac{\sin m(y, \phi_{01}) d\phi'}{1 + 2C_1 u(y, \phi_{01})} \right]
$$

$$
+ \cos m\phi_n \int_0^{2\pi} \frac{\cos m(y, \phi_{01}) d\phi'}{1 + 2C_1 u(y, \phi_{01})}
$$

(17)

The summation over $m$ represents the sum of all harmonic frequencies for each of the $n$ fundamental frequencies. Assuming that the circuit beam interactions at the harmonic frequencies are negligible and keeping only the $m = 1$ terms,
\[ \rho_n (y, \phi_0) = \frac{1}{u_0} \left[ \sin \phi_n \int_0^{2\pi} \sin \theta_n (y, \phi'_0) d\phi'_0 \right] 
+ \cos \phi_n \int_0^{2\pi} \frac{\cos \theta_n (y, \phi'_0) d\phi'_0}{1 + 2c_1 u(y, \phi'_0)} \]  

(18)

These values may now be substituted into the circuit equation to get Rowe's next two large-signal equations:

\[ \frac{d^2 A_n (y)}{dy^2} = A_n (y) \left[ \left( \frac{\omega_n}{\omega_1 c_1} - \frac{d\theta_n}{dy} \right)^2 - \left( \frac{\omega_n}{\omega_1} \right)^2 \left( \frac{1 + c_1 b_n}{c_1} \right)^2 \right] 
- \frac{2\pi}{Z_{01} (\omega_1)} \left( \frac{1 + c_1 b_n}{c_1} \right)^2 \left[ 2c_n d_n \int_0^{2\pi} \frac{\sin \theta_n (y, \phi'_0) d\phi'_0}{1 + 2c_1 u(y, \phi'_0)} \right] 
+ \int_0^{2\pi} \frac{\cos \theta_n (y, \phi'_0) d\phi'_0}{1 + 2c_1 u(y, \phi'_0)} \right] \]  

(19)

\[ \frac{d^2 \theta_n}{dy^2} \left[ \frac{2\pi}{2c_n d_n (\omega_1)} \left( \frac{1 + c_1 b_n}{c_1} \right)^2 \right] - 2 \frac{dA_n (y)}{dy} \left( \frac{\omega_n}{\omega_1 c_1} - \frac{d\theta_n}{dy} \right) 
- \frac{2\pi}{Z_{01} (\omega_1)} \left( \frac{1 + c_1 b_n}{c_1} \right)^2 \left[ 2\pi \sin \theta_n (y, \phi'_0) d\phi'_0 \right] 
+ \int_0^{2\pi} \frac{2\pi \cos \theta_n (y, \phi'_0) d\phi'_0}{1 + 2c_1 u(y, \phi'_0)} \right] \]  

(20)

Equation 19 is the circuit wave amplitude equation, and Eq. 20 is the circuit wave phase equation.
C. Electron Force Equation

Rowe's final large-signal equation is derived from the Lorentz force equation,

$$\frac{d^2 z}{dt^2} = \left| \frac{\partial V}{\partial z} \right| \left( \frac{\partial V}{\partial z} + \frac{\partial V_{sc}}{\partial z} \right)$$  \hspace{1cm} (21)

where $V_{sc}$ and $V_c$ are the space-charge and circuit terms, respectively. Using Eq. 9 and the chain rule for derivatives and substituting into Eq. 21 yields

$$\frac{\partial u(y, \theta_{01})}{\partial y} \left[ 1 + 2C \frac{u(y, \theta_{01})}{u_0} \right] = \frac{|n|}{2C \omega_1 u_0} \left\{ \frac{Z_0 I_0}{C_1} \frac{1}{n} \left[ \frac{dA_n(y)}{dy} \cos \theta_n \right. \right.$$

$$- A_n(y) \sin \theta_n \left( \frac{\omega_n}{\omega_1 C_1} - \frac{d\theta_n}{dy} \right) \left. \right\} - \frac{1}{\omega_1} E_{sc}$$  \hspace{1cm} (22)

where $E_{sc}$ is the space-charge field. The constant in front of the circuit wave term can be simplified using the definition of Pierce's gain parameter,

$$\frac{\partial u(y, \theta_{01})}{\partial y} \left[ 1 + 2C \frac{u(y, \theta_{01})}{u_0} \right] = C \frac{\gamma}{n} \left[ \frac{dA_n(y)}{dy} \cos \theta_n - A_n(y) \sin \theta_n \left( \frac{\omega_n}{\omega_1 C_1} - \frac{d\theta_n}{dy} \right) \right]$$

$$- \frac{|n|}{2C \omega_1 u_0} E_{sc}$$  \hspace{1cm} (23)

Rowe derived a space-charge expression,

$$E_{sc} = - \frac{2 \omega_1 u_0}{\left| 1 + \frac{C}{n} \right|} \left( \frac{\omega}{\omega_1} \right)^2 \frac{1}{\gamma} \int_0^{2\pi} F(\theta - \theta_{01}) d\theta_{01}$$  \hspace{1cm} (24)

- 10 -
where $F(\theta - \phi_{01})$ is a space-charge weighting function derived by Poulter. Rove developed a closed form expression for this function:

$$F(\theta - \phi_{01}) = \frac{1}{2\pi} \left[ \frac{\pi - (\theta - \phi_{01})}{2} - 2 \tan^{-1} \frac{\sin (\theta - \phi_{01})}{\sqrt{e^2 b^2 f(a'/b')}} \cos (\theta - \phi_{01}) + \tan^{-1} \left( \frac{\sin (\theta - \phi_{01})}{\sqrt{e^2 b^2 f(a'/b')}} \cos (\theta - \phi_{01}) \right) \right]$$

for $0 < (\theta - \phi_{01}) < 2\pi$ (25)

where $a'$ and $b'$ are the helix and beam radii, respectively, and

$$f(a'/b') = \frac{\partial \ln (1 - R_n)}{\partial b'} \text{ at constant } a'/b'$$

(26)

where $R_n$ is the electron plasma frequency reduction factor,

$$R_n^2 \left[ 1 - \frac{8b'}{I_0(8a')} \right] \left[ I_1(8b') K_0(8a') + I_0(8a') K_1(8b') \right]$$

(27)

where $I_n$ and $K_n$ are modified Bessel functions. Substituting the space-charge expression into Eq. 22 yields the fourth and final large-signal equation.

$$\frac{\partial u(y, \phi_{01})}{\partial y} [1 + 2C_1 u(y, \phi_{01})] = C_1 \sum_n \left[ \frac{\partial A_n(y)}{\partial y} \cos \phi_n - A_n(v) \sin \phi_n \left( \frac{\omega_n}{\omega_1 c_1} - \frac{\partial \phi_n}{\partial y} \right) \right]$$

$$+ \left( \frac{1}{1 + C_n \nu_n} \right) \left( \frac{\omega_n}{\omega_1 c_1} \right)^2 \int_{0}^{2\pi} F(\theta - \phi_{01}) d\phi_{01}$$

(28)
D. Initial Conditions

The solution of Rowe's large-signal equations may be treated as an initial-value problem if it is assumed that the helix is terminated in its characteristic impedance so that there are no reflections at the output. The initial conditions for the beam and circuit wave are derived in this section. In deriving these conditions, it was assumed that the electron beam is unmodulated at the input.

At the input to the tube ($y = 0$), there is no RF interaction, so the second derivatives are zero. Also, since the beam is unmodulated at the input, the space-charge terms are zero. Thus, the circuit wave phase equation becomes

$$\frac{d\theta_n^0}{dy} = -\frac{C_n b_n}{1 + \frac{\omega}{C_n}}$$  (29)

Substituting this into the circuit wave amplitude equation at the input yields

$$\frac{dA_n(y)}{dy} = -A_n(y)C_n d_n \left(\frac{\omega}{1 + \frac{\omega}{C_n}}\right) \cdot 1 + C_n b_n$$  (30)

The unmodulated beam at the input is represented by uniformly distributing the electron charge groups over one cycle of the fundamental frequency. For $n$ charge groups, the initial phases are given by

$$\phi_{0,i} = \frac{2\pi i}{n}, \quad i = 0, 1, 2, \ldots, n$$  (31)
The velocity of the beam at the input is equal to the dc stream velocity, so that

\[ 1 + 2C_l u(0, \theta_0, j) = 1 \]  

(32)
III. ATTENUATORS AND SEVERS

Virtually all helix traveling-wave tubes use attenuators and/or severs to prevent oscillations. Therefore, any program used for the design of these tubes must be able to model circuit loss.

The simplest way to model loss in a traveling-wave tube is to increase Pierce's loss parameter, $d$. This is the method recommended by Rowe.\textsuperscript{7} Figure 2 shows the result of various Gaussian shaped attenuators on output power, and Fig. 3 shows the result for a region of uniform loss. As we would expect, the attenuators increase the saturation length without decreasing the saturation power. (This would not be the case if the attenuator was too close to the output.)

Unfortunately, there is a problem with this method of modeling loss in a circuit. It will lead to instabilities for large values of loss. This is due to the fact that both the propagation constant, $B$, and the impedance, $Z$, vary with the resistance in the circuit. The change in $B$ causes the circuit wave to lose synchronism with the beam, and the change in $Z$ causes reflections in the attenuator due to the impedance mismatch. The result of these problems is that the circuit wave phase angle oscillates in a region of heavy attenuation. This is illustrated in Fig. 4. The higher the loss and/or the longer the region of attenuation, the greater the oscillations. In order to work around this problem in the model, attenuators are replaced by severs when their loss exceeds a certain level.
Fig. 2. Gaussian shaped attenuators.

Fig. 3. Uniform attenuators.
Fig. 4. Oscillation of circuit-wave phase in an attenuator.
In fact, the effect of a strong attenuator is much the same as that of a sever. In a sever, the circuit wave is eliminated and the beam drifts down the tube affected only by the space-charge forces. Similarly, a strong attenuator will diminish the circuit wave so much that the electron beam is unaffected by it. Thus, it is reasonable to model a region of strong attenuation with a sever.

The equations inside the sever are simply Rowe's large-signal equations with the circuit wave terms removed,

\[
\frac{3u(y, \phi_{01})}{\delta y} \left[ 1 + 2C_1 u(y, \phi_{01}) \right] = \left( \frac{\omega_p}{\omega_l C_1} \right)^2 \left( \frac{1}{1 + \frac{C_1 b}{\omega_n}} \right) \int_0^{2\pi} \frac{F(\phi - \phi_{01}) d\phi_{01}}{1 + 2C_1 u(y, \phi_{01})}
\]

\[
\frac{3\phi_n(y, \phi_{01})}{\delta y} = 2 \left( \frac{\omega_n}{\omega_l} \right) \left( \frac{u(y, \phi_{01})}{1 + 2C_1 u(y, \phi_{01})} \right)
\]

(33)

(34)

The first equation is the electron force equation, and the second is the electron phase equation. Once inside a sever, the circuit wave phase, the circuit wave amplitude, and their derivatives are zero. The remaining two drift tube equations are integrated through the sever.

At the end of the sever, the circuit wave must be restarted. Rowe\textsuperscript{7} suggests that the following initial conditions be used: \( A_n(y) = 0 \), \( \theta_n(y) = 0 \), and \( d\theta_n(y)/dy = -\frac{\omega b c}{\omega_n C_1} \). However, the last condition requires the beam to be unmodulated (Eq. 28). In fact, the beam is highly modulated in the sever, and it is this modulation that restarts the circuit wave. I suggest the following conditions for the end of a
sever. Since there is no RF interaction in the sever, the second derivatives are zero. So the circuit wave phase equation becomes

\[
\frac{d\theta_n(y)}{dy} = \frac{\omega_n}{\omega_1 C_1} - \left(\frac{\omega_n}{\omega_1 C_1}\right)^2 - \frac{1}{A_n(y)} \left(\frac{Z_{0n}}{C_1}\right) \left(\frac{\omega_n}{\omega_1}\right) \left(\frac{1 + C_n b_n}{C_1}\right) \left[ \int_0^{\varphi_0} \frac{2\pi \cos \phi (y, \dot{\varphi}') \, d\phi'}{1 + 2C_1 u(y, \dot{\varphi}'_0)} + 2C_n d_n \int_0^{\varphi_0} \frac{2\pi \sin \phi (y, \dot{\varphi}') \, d\phi'}{1 + 2C_1 u(y, \dot{\varphi}'_0)} \right]
\]

(35)

and the circuit wave amplitude equation becomes

\[
\frac{dA_n(y)}{dy} = \left(\frac{\omega_n}{\omega_1}\right)^2 \left(\frac{1 + C_n b_n}{C_1}\right) \left(\frac{d\theta_n}{dy} - \frac{\omega_n}{\omega_1 C_1}\right)^{-1} \left[A_n(y)C_n d_n \left(\frac{1 + C_n b_n}{C_1}\right) + \left(\frac{Z_{0n}}{C_1}\right) \left(\frac{\omega_n}{\omega_1}\right) \left(\frac{1}{2\pi}\right) \left[ \int_0^{\varphi_0} \frac{2\pi \sin \phi (y, \dot{\varphi}') \, d\phi'}{1 + 2C_1 u(y, \dot{\varphi}'_0)} - 2C_n d_n \int_0^{\varphi_0} \frac{2\pi \cos \phi (y, \dot{\varphi}') \, d\phi'}{1 + 2C_1 u(y, \dot{\varphi}'_0)} \right] \right]
\]

(36)

Note that Eq. 35 has the circuit wave amplitude, \( A_n(y) \), in the denominator. This prevents us from assigning a value of zero to this variable at the end of a sever. Instead of zero, the maximum of 1 percent of the input value or 1 percent of the present value of \( A_n \) is used. This value is large enough to prevent numerical overflow, yet small enough to realistically model a sever. The power and circuit wave phase are plotted using both Rowe's and the new initial conditions at the end of a sever in Figs. 5 and 6. As the figures show, the new initial conditions greatly reduce the oscillations in the circuit phase plot and eliminate them completely in the power plot.
Fig. 5. Power plot of a Gaussian shaped sever.

Fig. 6. Phase plot of a Gaussian shaped sever.
Figure 7 shows the result of an abrupt sever. Note that after the sever, the power rapidly grows to a level approximately 6 dB below what it would have been without the sever. This result is in agreement with Pierce\textsuperscript{5} and experimental results.

Fig. 7. Power plot of an abrupt sever.
IV. COMPUTER IMPLEMENTATION OF ROWE'S EQUATIONS

This section describes how the large-signal equations derived in the previous sections are set up and solved in TWTlD. In addition, it shows how the program is organized, and how attenuators, severs, velocity steps, and tapers are handled. TWTlD is composed of a main program block and 23 subprograms. The program blocks can be grouped according to the functions they serve, as illustrated in Table 1.

Table 1. TWTlD program blocks organized by function.

A. Program Control

TWTID is set up to integrate Rowe's large-signal equations down a tube, with stops for attenuators, velocity changes, and restart data printouts. At each of these stops, the appropriate subroutine is called to implement the change in parameters or the printout. The flow of the program is controlled by the main program block and subroutines ZSORT, EVENT, and INTSUB.

The main program block is divided into 9 sections. The first section sets up the arrays, variables, and constants used in the main program and various subprograms. The second section controls the terminal display and keyboard input when the program is run. The third section reads the data from the input data file. In addition, the attenuators and velocity tapers are set up in this section. The next section converts the input data into Pierce parameters and normalized Rowe variables. Section 5 reads the restart data or, if no restart data are available, initializes the beam and circuit wave. In Section 6, the output data file is opened, and the Pierce parameters computed in Section 4 are printed out. In order to facilitate the program flow, Section 7 puts all events that require stopping the integration into a single list, sorted according to their position along the circuit. These events are restart data printouts, attenuators, and velocity steps and tapers. The eighth section controls the actual flow of the program. It moves down the axial position list, integrating Rowe's large-signal equations. At each event, the integration is stopped, the type of event is determined, and the appropriate subroutine called. The last
section computes and prints out the saturation power, gain, efficiency, and length. The output files are then closed, and program execution stops.

Subroutine ZSORT does the actual sorting of the axial position list. It creates two lists: one of stop positions, ZSTOP(i), and one of event type codes corresponding to the stop positions, SWLIST(i). Each event type is assigned a specific prime number code. When more than one event occurs at a position, the event type codes are multiplied. Thus, the numbers can be factored to determine which events occur at each stop position.

Subroutine EVENT checks the event code at each stop position to determine which events occur. The event codes used are: 2 Print restart data; 3 Start attenuator; 5 Stop attenuator; 7 velocity change.

The control code in the main program block stops the integration of the large-signal equations for attenuators, velocity changes, and restart data printouts. However, the integration must also be stopped for the output printouts. Subroutine INTSUB accomplishes this by breaking up tube sections between successive stop events into print intervals. At each print interval, subroutines are called to integrate Rowe's equations and print the output data. In addition, INTSUB ensures that the equations are integrated to the end of the section.

8. Rowe's Large-Signal Equations

Rowe's circuit wave amplitude and circuit wave phase equations are second order differential equations. However, the differential equation
The solver used in TWTID solves only first order differential equations. Moreover, the equations must be of the form,

\[ \begin{array}{c}
  y'_1(t) = f_1(t, y_1(t), v_2(t), \ldots, v_n(t)) \\
  y'_2(t) = f_2(t, y_1(t), v_2(t), \ldots, v_n(t)) \\
  \vdots \\
  y'_n(t) = f_n(t, y_1(t), v_2(t), \ldots, v_n(t)) \\
\end{array} \]  

So, the equations must be manipulated to fill these requirements. Let

\[ \frac{dA_n(y)}{dy} = G_n(y) \quad \text{and} \quad \frac{d\theta_n(y)}{dy} = F_n(y) \]  

then

\[ \frac{d^2A_n(y)}{dy^2} = \frac{d^2G_n(y)}{dy^2} \quad \text{and} \quad \frac{d^2\theta_n(y)}{dy^2} = \frac{d^2F_n(y)}{dy^2} \]  

Substituting these new variables into Rowe's equations and rearranging yields

\[ \frac{d\theta_n(y, \phi_{01})}{dy} = 2\left(\frac{\omega_n}{\omega_L}\right) \frac{u(y, \phi_{01})}{1 + 2C_1 u(y, \phi_{01})} - F_n(y) \]  

\[ \frac{dA_n(y)}{dy} = G_n(y) \]  

- 24 -
\[
\frac{dG}{dv} = A_n(v) \left( \frac{\omega_n}{\Omega} - F_n(v) \right) + A_n(v) \left( \frac{\omega_n}{\Omega} - F_n(v) \right) \left( \frac{n + \sin \theta}{n + \sin \theta} \right)
\]

(42)

\[
\frac{dF}{dv} = 2C_n d_n \left( \frac{n + \sin \theta}{n + \sin \theta} \right) - A_n(v) \left( \frac{\omega_n}{\Omega} - F_n(v) \right) \left( \frac{n + \sin \theta}{n + \sin \theta} \right)
\]

(43)

These are the differential equations that are set up and evaluated at subroutine \text{DIFSEP}, \text{DIFF}, \text{DRFTEQ}, and \text{DRIFT}. The subroutines also set the initial conditions for the large-signal equations.

Subroutine \text{DIFSEP} contains Rowe's differential equations. The computer names used for the various variables are given in Table 2.

- 26 -
This subroutine is used by the differential equations solver to evaluate the derivatives. After the equations are evaluated, they are stored in a single array called EQU. The solutions to the equations are stored in the array, VALUES.

Subroutine DIFF sets the initial conditions for the differential equations and calls the differential equation solver. The parameters passed to the solver are the subroutine used to evaluate the derivatives, DIFF, the number of equations to be integrated, NNU, the array of solutions, VALUES, the independent variable, Y; the position where the solution is desired, XINT, the relative and absolute local error tolerances RELERR and ABSErr, the flag to initialize solver, IFLAG, and the flag to set the machine dependent variable, SET.

Subroutine DRIFT contains the differential equations for a drift time. It is used by the differential equation solver to evaluate the derivatives when integrating through a sever. As in subroutine DIFF, the equations are stored in a single array called EQU, and the solutions to the equations are stored in the array, VALUES.

Subroutine DRIFT performs the same duties for DRIFT that DIFF performs for DIFF.

C. Integrals in Rowe's Differential Equations

The circuit wave amplitude, the circuit wave phase, and the electron force equations each contain integrals that must be solved at every step of the differential equation solution. These integrals are solved in subroutines FINIT, INT1, AND INT2.
Subroutine RINT solves the two integrals that arise from the Fourier series expansion of the beam charge density. Since the electron disks are evenly spaced over 10 radians initially, the integration over phase can be replaced with an integration over all the electron disks. Moreover, the discrete number of electron disks used in the computer model allows the integrals to be replaced by summations. These summations are conducted once at each step of the differential equation solution.

Subroutine INTI solves the integral from the space-charge field expression. As in the beam charge density integrals, this integral is replaced by a summation over the electron disks. The space-charge summation must be conducted for each electron disk at each step.

Subroutine INT2 solves the polynomial approximation to the space-charge integral. This subroutine runs in about half the time that INTI takes to run. Since the space-charge integral is evaluated so often, using the polynomial approximation can make a significant difference in run time.

D. Numerical Analysis

Numerical analysis routines are used to solve Rowe's large-signal equations and to calculate Bessel functions for Pierce's gain parameter. The numerical analysis routines are DESOLV, STEP, INTRP, MACHIN, and BESSEL.

The differential equation solver used in TWT1D was taken from a text by L. F. Shampine and M. K. Gordon. The solver is a variable step, variable order Adams code. It consists of routines DESOLV, STEP,
INTRP, and MACHIN. Subroutine DESOLV is a driver that calls the other subroutines in the solver. MACHIN computes the machine unit roundoff error, U, which is the smallest positive number such that 1.0 + U > 1.0. Subroutine STEP integrates the differential equations one step, and subroutine INTRP approximates the solution at the end point by evaluating the polynomial there. The code is completely explained and documented in the text by Shampine and Gordon, and those interested in the code should consult that text.

Subroutine BESSEL calculates modified Bessel functions of the first and second kind.

E. Program Output

As Rowe's equations are integrated down the traveling-wave tube, various parameters describing the tube's performance are printed to output data and plot files and displayed on the terminal. In addition, variables describing the beam and circuit wave must be printed for a restart printout. The subroutines that handle this are OUTPUT and OUTRS.

Subroutine OUTPUT controls the output of data at each print interval. It prints the axial position, power, and phase angle to the plot file, and displays the position and power on the terminal. The NPR variable is used to determine which variables are printed to the output data file. In addition, OUTPUT uses the power and its derivative with respect to position to calculate the saturated power.

Subroutine OUTRS controls the restart printouts. A restart output is used when an engineer wants to examine the effect of different output
helices without having to run the input helix in each case. The circuit wave variables printed out are normalized position, $Y$, circuit wave amplitude, $A(n)$, its derivative, $DA(n)$, circuit wave phase, $THETA(n)$, and its derivative, $DTHETA(n)$. The beam variables printed out are electron phase positions, $PHI(i,n)$, and electron velocities, $U(i)$. In addition, if the polynomial approximation to the space-charge function is used, its coefficients, $CB(m)$ are printed out. These data contain the information needed to restart a run at that position.

F. Circuit Changes

Whenever a change in circuit velocity or loss occurs, the parameters describing the circuit must be recomputed. Subroutine ATTEN handles changes in loss due to attenuators or severs, and subroutine CHANGE handles changes in velocity due to velocity steps or tapers.

Attenuators are broken into 20 sections in the main program. In each section, subroutine ATTEN adjusts Pierce's loss parameter, calls a subroutine to integrate the large-signal equations, and checks the event code list to see if any velocity changes or restart printouts occur in the section. If the loss in a section exceeds 170 dB, the section is treated as a sever, and the drift tube equations are integrated. At the end of the sever, the subroutine sets initial conditions and integrates the large-signal equations. After all the sections are integrated, the loss parameter is reset to its original value.

Subroutine CHANGE first checks to see if the velocity change includes a change in helix radius. If so, the fill factor is rescaled, and the voltage, beam velocity, and plasma frequency are recalculated.
The phase velocity of the new helix section is used to recalculate the propagation constants, the axial impedance is used to recalculate the Pierce's gain and velocity parameters, and the circuit loss is used to recalculate Pierce's loss parameter. Using the new values, the normalized helix voltage and its derivative are rescaled, and the plasma frequency reduction factor and the space-charge parameter are recalculated. Finally, the axial position, the length of the tube, and the print interval are renormalized.

**G. Diagnostics**

Subroutines ENERGY and BADIN are provided for diagnostic purposes. These subroutines can help indicate whether or not the model used is reasonable, or if the input file has incorrect data.

Subroutine ENERGY checks to see if energy is conserved in the computer model. It calculates the power lost by the beam, EBEAM, and the power contained in the circuit and its fields, EWAVE. In addition, it computes an energy balance, EBLNC = (|EBEAM| - |EWAVE|)/(|EBEAM| + |EWAVE|). If the model is a reasonable simulation, EBLNC will be near zero. However, this routine does not account for the circuit wave power lost in attenuators so, in these regions, EBLNC will not be near zero.

Subroutine BADIN is called when the input to subroutine DESOLV is incorrect. When called, BADIN prints an error message to the screen and halts program execution. This subroutine will be called only if the input data file has incorrect data.
H. Rowe's Space-Charge Expression

Rowe's space-charge weighting function is very complex and expensive to evaluate. In fact, the majority of the computer time used during a run is spent evaluating and integrating this function. In order to reduce the amount of time spent computing the space-charge forces, the space-charge weighting function can be represented by a series expansion. The subroutines that generate the series expansion are SPACE and SIMINT.

The expansion of a function, \( f(x) \), in a series of Chebyshev polynomials is given by

\[
f(x) = \frac{a_0}{2} + \sum_{i=1}^{\infty} a_i T_i(x)
\]  

(46)

where \( T_i(x) \) are the Chebyshev polynomials and

\[
a_i = \frac{2}{\pi} \int_{-1}^{+1} \frac{f(x)T_i(x)}{\sqrt{1 - x^2}} \, dx
\]

(47)

Over the interval \((0, 2\pi)\), the function becomes

\[
F(\phi - \phi_0) = \frac{a_0}{2} \sum_{i=1}^{\infty} a_i T_i(x)
\]

(48)

where

\[
a_i = \frac{2}{\pi} \int_{-1}^{+1} \frac{F(\pi(x + 1))T_i(x)}{\sqrt{1 - x^2}} \, dx
\]
and

\[ x = \frac{\phi - \phi'}{01} - 1 \]

As Fig. 8 shows, Rowe's space-charge function is odd. Therefore, only the odd order terms are used for the series expansion. For a fifth order expansion, the series is

\[ F(\phi - \phi') = a_1 T_1 \left( \frac{\phi - \phi'}{01} - 1 \right) + a_3 T_3 \left( \frac{\phi - \phi'}{01} - 1 \right) + a_5 T_5 \left( \frac{\phi - \phi'}{01} - 1 \right) \]

(49)

Fig. 8. Rowe's space-charge function.
where

\[ a_1 = \frac{2}{\pi} \int_{-1}^{1} \frac{F(\pi(x + 1))x}{\sqrt{1 - x^2}} \, dx \]

\[ a_3 = \frac{2}{\pi} \int_{-1}^{1} \frac{F(\pi(x + 1)) \left(4x^3 - 3x\right)}{\sqrt{1 - x^2}} \, dx \]

\[ a_5 = \frac{2}{\pi} \int_{-1}^{1} \frac{F(\pi(x + 1)) \left(16x^5 - 20x^5 + 5x\right)}{\sqrt{1 - x^2}} \, dx \]

This expression is plotted along with Rowe’s space-charge function for the case of \( f(a'/b') = 1.25 \) in Fig. 9. As the figure shows, the agreement between the two functions is very good. Figure 10 compares results
Fig. 10. Power plot using the polynomial approximation.

of a TWT1D run using the full space-charge expression to a run on the same tube using the polynomial approximation. The results of the two runs are almost identical, but the run using the approximation took only half the time of the run using Rowe's full space-charge expression.

Subroutine SPACE calculates the coefficients for the polynomial approximation using the function SIMINT. SIMINT solves the integral for the coefficients using Simpson's integration.
V. RESULTS AND CONCLUSION

In this section, the validity of TWTID is investigated. Two Teledyne MEC tubes were simulated by the program, and the results are compared to the measured output of the tubes.

The first tube modeled is an I/J band pulse tube. It has 6 attenuators, 4 pitch changes, and a diameter step. The tube was simulated, using 16 electron disks and Rowe's full space-charge expression. Several runs of the program were made to determine the saturated power across the band. The results of the program and the measured output power are plotted in Fig. 11. As the figure shows, the agreement across the band is very good. However, at the low end of the band, the predicted power is 1 to 2 dB higher than the measured output. In order to correct this, the program was rerun for the first three data points with the harmonic included. Since the tube is a broadband device, harmonics can have a significant effect on the output power at the low end of the band. The results of the runs with the harmonic included are shown in Fig. 12. As this figure shows, the harmonic does lower the saturated power and brings the 2 curves into closer agreement at the lower frequencies.
Fig. 11. Saturated power for an I/J band tube.

Fig. 12. Saturated power for an I/J band tube with harmonic.
The second tube modeled is an E/H band CW tube. It has 3 attenuators and 2 pitch changes. The tube was simulated, using 16 electron disks and the polynomial approximation to the space-charge expression. The results of the runs and the measured output are plotted in Fig. 13. Again, the agreement between the two curves is very good.

The simulations of the two tubes indicate that TWTID can be a useful tool for the design engineer. However, care must be taken whenever a nonlinear program is used. Many of the parameters that are used by such a program, such as the fill factor and the axial impedance, are not precisely known to the engineer. Yet these parameters have a large effect on the output of the program. Figure 14 shows the results that changing the fill factor can have on the output of the program. Note that changing the fill factor from 0.4 to 0.6 moves the saturation position as much as 2 inches.

Perhaps the biggest problem with any large-signal program based on Rowe's approach is the way it models attenuators. As was discussed in Section III, attenuators cause oscillations in the circuit wave phase angle. This problem was circumvented in TWTID by replacing attenuators with severs, but that is not a complete solution. This problem should be solved before more elaborate models of Rowe's approach are attempted.

1. Introduction

TWTID is a one-dimensional large-signal analysis program for helix travelling-wave tubes based on the theory developed by L. E. Price and M. K. Scherba. The program can be used to predict the performance of a helix travelling-wave tube before it is assembled. The input to the program consists of information about the beam, the input signals, and the helix. Parameters describing the helix are typically obtained from cold circuit testing, while information about the beam can come from beam analyzer results or computer design data. Prior to running TWTID, the engineer creates an input data file which lists these parameters. This manual describes how this file is to be created and how to run TWTID. Complete documentation for the program, including a source code listing, is given in AFTER report No. 17, available from the Electrical Engineering Department at the University of Utah.

2. Input Data File

The input file should be organized along the lines of Fig. A.1. The number of lines in the file is variable and is determined by the number of frequencies, velocity steps, attenuators, etc., present in the tube being modeled. The key following Fig. A.1 describes each of the variables listed in the input file, and Fig. A.2 shows a sample input file. Since the input files can become lengthy, it is strongly recommended that before using TWTID, the input data file be checked with the
program TWTIN. TWTIN is a short program which reads TWT10 input files and lists the parameters so that the engineer can verify the input being used. The sample input file shown in Fig. A.3 was checked with TWTIN, and the result is shown in Fig. A.4.

</tr>
</tbody>
</table>

The space-charge switch determines how the repulsive force between electrons is calculated. If the tube has low beam current density, or quantitative results are not required, then it is appropriate to ignore the space charge and set SCS to 0. If the tube has few circuit changes and a small step size, the polynomial approximation to the space charge will give reasonable results, and SCS should be set to 2. For highest accuracy, SCS should be set to 1 so Rowe's full space-charge expression is used.

Fig. A.4. TWTIN run for sample input file.
3. Running the Program

Once an input file has been created and checked, the engineer is ready to run TWTID. When run, the program prompts the user for the name of the input data file, the output data file, and the plot file. The output data file is where all the data from the run will be stored, and the plot file will contain the data needed to make plots of power versus position, and phase angle versus position. Although any name can be used for the output and plot files, the user is cautioned against using names of existing files. That can result in the original contents of those files being lost. It is recommended that the names of the output and plot files be related to each other so that it is easy to recall which plot file corresponds to which output file. For example, if the input file is called RUN1.DAT, the output and plot files could be named RUN1.OUT and RUN1.PLT, respectively. Figure A.5 shows the terminal display for a TWTID run. As the program runs, the axial position and power will be printed to the terminal.
4. Output Data File

The TWTID output file for the sample input file is shown in Fig. A.6. Notice that at each print interval, several variables describing the performance of the TWT are printed to the output file. Which variables are printed is determined by the variable, NPR, in the input data file. The four options available are described and illustrated in this section.

TWTID 1:35 PM MON., 20 JAN., 1986

Fig. A.6. TWTID output file.
NPR = 1

This is the printout option which will most often be used by tube designers. It prints out the following variables.

- **Z**: Axial position (in)
- **PDB**: Power (dBm)
- **B**: Pierce’s velocity parameter
- **THETA**: The phase angle of the circuit wave (radians)
- **DPDB**: The partial derivative of power with respect to position
- **DTDZ**: The partial derivative of phase angle with respect to position
- **ETA**: The efficiency
- **D**: Pierce’s loss parameter

**NPR = 2**

This option prints out all the variables in NPR = 1, as well as information about energy in the beam and in the circuit wave. This can help indicate whether or not the computer simulation is a good representation of the physical process. The variables are:

- **EBEAM**: Power lost by the beam, normalized by the total beam power
- **EWAVE**: Power contained in the circuit wave and in the field between the circuit and the beam
- **EBLNC**: \((|\text{EBEAM}| - |\text{EWAVE}|) / (|\text{EBEAM}| + |\text{EWAVE}|)\)

If the simulation is reasonable, EBLNC will be near zero. A "good" value for EBLNC is on the order of 0.1. However, this parameter does not account for the circuit wave power lost in attenuators so, in those regions, EBLNC will not be near zero.
NPR = 3

This option includes all the variables in NPR = 1, as well as information for creating electron flight diagrams and Cutler charts. The variables are:

PHI(i,l)  Electron phases for the fundamental frequency
2*C(1)*U(i)  Normalized electron velocities

NPR = 4

This option will print out all the variables listed above. It generates a lot of data! All of the NPR options are illustrated in Fig. A.7.

Fig. A.7. TwTl0 printout options.
1. Restarting a Run

Often an engineer will want to examine the effect of different input helices on a tube's performance. TWTID allows the user to do this without having to rerun the input helix in each case.

If a run is to be restarted, the input file for the initial run should have the number of restarts, NUMR set to 1, and the position of the restart printout, RST, set to the position of the restart. The output file for that run will contain all the information needed to restart the run. A restart printout at 4.5 inches is illustrated in Fig. A.6. To restart the run, the data from the restart must be appended to the original input file, and the restart data input switch, RSTART, set to 1. Figure A.8 shows the input file for a restarted run. Note that all the character data have been removed from the restart data.

MISSION
of
Rome Air Development Center

EADC plans and executes research, development, test and selected acquisition programs in support of Command, Control, Communications and Intelligence, C3I activities. Technical and organizational support within areas of competence is provided to ESC Program Offices (POs) and other ESC elements to perform effective acquisition of C3I systems. The areas of technical competence include communications, command and control, battle management, information processing, surveillance sensors, intelligence data collection and handling, fixed state sciences, electromagnetics, and integration, and electronic, maintainability, and survivability.
