ERIC: AN OBJECT-ORIENTED SIMULATION LANGUAGE

Michael L. Hilton, 1Lt, USAF

APPROVED FOR PUBLIC RELEASE; DISTRIBUTION UNLIMITED

ROME AIR DEVELOPMENT CENTER
Air Force Systems Command
Griffiss Air Force Base, NY 13441-5700
This report has been reviewed by the RADC Public Affairs Office (PA) and is releasable to the National Technical Information Service (NTIS). At NTIS it will be releasable to the general public, including foreign nations.

RADC-TR-87-103 has been reviewed and is approved for publication.

APPROVED:  

SAMUEL A. DINITTO, JR.  
Chief, C2 Software Technology Division  
Directorate of Command and Control

APPROVED:  

RAYMOND P. URTZ, JR.  
Technical Director  
Directorate of Command and Control

FOR THE COMMANDER:  

RICHARD W. POULIOT  
Directorate of Plans & Programs

If your address has changed or if you wish to be removed from the RADC mailing list, or if the addressee is no longer employed by your organization, please notify RADC (COPS) Griffiss AFB NY 13441-5700. This will assist us in maintaining a current mailing list.

Do not return copies of this report unless contractual obligations or notices on a specific document require that it be returned.
ERIC: AN OBJECT-ORIENTED SIMULATION LANGUAGE

Michael L. Hilton, 1Lt, USAF

ERIC is an object-oriented programming language designed to support intelligent simulations. This report describes the ERIC language. ERIC supports the construction of software "objects" that model objects in the physical world. These software objects can be combined to form simulations which are characterized by a high degree of flexibility and perspicuity.
ERIC is an object-oriented programming language designed for supporting the development of intelligent, discrete, event-driven simulations. ERIC was developed as part of an on-going research effort at the Rome Air Development Center to build a new generation of knowledge-based simulations that support Battle Management studies.

Object-oriented programming languages are designed to support the development and maintenance of large, complex software systems. These systems are composed of objects which have certain attributes and behaviors. Objects communicate with each other by message passing. The object-oriented paradigm is particularly useful for modelling and simulation because many real-world systems are composed of objects whose interactions can be represented by messages.

This report is a description of the ERIC programming language. It does not assume the reader is familiar with object-oriented programming or simulation; however, it does assume that the reader is familiar with Lisp.

Chapter 1
Objects, Classes, and Inheritance

1.0 Objects

Objects are software entities that model real-world things. They combine the properties of both data and procedures: objects maintain a local state and are capable of performing computations using and/or modifying their local state.

The local state of an object consists of its attributes. Attributes describe characteristics of an object. For example, an object modelling an automobile might have color, engine size, and number of doors as attributes.

An object performs computation via behaviors. A behavior is a piece of procedural code associated with a given object or group of objects. Each behavior is identified by a particular message, which will invoke the behavior when the message is received by an object. For example, an automobile object might be sent a message telling it to start its engine. Message passing is how objects in ERIC interact with each other and the user. Message passing is one of the most important characteristics of ERIC and will be examined in more detail in Chapter 2.
There are two types of objects in ERIC: class objects and instance objects. A class is a description of one or more similar objects. In other languages, such as Pascal, classes correspond to types. An instance is an actual member of a class. For example, 3 is an instance of the class integer. A class can be a member, or subclass, of a more general class. Integers are a subclass of numbers. The ability to build more specific classes (such as integers) out of a more general class (numbers, in this case) is a powerful abstraction mechanism. ERIC provides this mechanism via class inheritance. A subclass can inherit attributes and behaviors from one or more superclasses.

[For the rest of this manual, use of the term "instance object" will be restricted to only those members of a class that are not themselves classes. In the numbers example given above, 3 will be considered an instance object, but integer will not. Also, the terms class and class object will be used interchangeably.]

1.1 Classes

Classes are used to model the organization of a system being simulated by an ERIC program. The system is decomposed into various real-world objects, and this decomposition is mapped onto software objects. More often than not, class objects are defined that are never actually instantiated. These class
objects exist purely for organizational reasons. This fact reflects an important insight into the implementation of object-oriented simulations: class objects should be used to organize and manage the objects in a simulation; they should not be an operational part of it. A careful examination of the system being simulated is necessary in order to determine which classes should be organizational in nature, and which classes should actually be instantiated.

There is a predefined class in ERIC called something. All other classes are built on top of (and hence, are subclasses of) something. Something provides many basic behaviors for all objects, such as how to print out attributes, make instances, or define new behaviors. New classes are defined in ERIC by using the define-class special form:

```
(define-class name
  (:parents superclass+)
  {(:documentation form})
  {(:instance-attributes \variable\ |
    (variable \init-value\))\*})
  {(:class-attributes \variable\ |
    (variable \init-value\))\*})
```

Example 1 shows several class definitions. This example will be referred to several times in the following discussion.

The :parents list is the only required information for defining a new class. It specifies the new class' inheritance chain. This chain determines which attributes and behaviors will be inherited from other classes. In Example 1, both fish and mammal have something as the only superclass in their inheritance
chain. Marine-mammal, however, has three superclasses in its chain: fish, mammal, and something, in that order. Notice that something is included in the inheritance chain even though it was not explicitly included in marine-mammal's :parents list. The order of the superclasses in the inheritance chain is very important, because this order determines what attributes and behaviors an object inherits.

Example 1
Sample Class Definitions

(define-class fish
  (:parents something)
  (:class-attributes
   (environment 'water))
  (:instance-attributes
   genus
   species
   common-name
   length))

(define-class mammal
  (:parents something)
  (:class-attributes
   (environment 'land))
  (:instance-attributes
   genus
   species
   common-name
   (length 'long)))

(define-class marine-mammal
  (:parents fish mammal)
  (:instance-attributes
   (weight '2-tons)))
Three rules govern the ordering of the inheritance chain:

1. A class always precedes its own superclasses.
2. The local ordering of superclasses in every object's :parents list is preserved.
3. Duplicate classes are removed from the ordering.

In Example 1, the inheritance chain for fish and mammal are trivial; they are [fish, something] and [mammal, something], respectively. The inheritance chain for marine-mammal is a bit more complex. Following the above three rules, we will construct marine-mammal's inheritance chain. The chain begins with marine-mammal (Rule 1). Next, we add fish and its inheritance chain. So far, the (incomplete) chain is:

[marine-mammal, fish, something...]

The next class in the parents list is mammal. Upon examining the inheritance chain of mammal, we discover that something is a superclass of mammal. According to Rule 1, we must place mammal before something. The chain is now:

[marine-mammal, fish, mammal, something...]

Continuing, we add the rest of the inheritance chain for mammal, which consists of something, to the end of the partial chain. We now have:

[marine-mammal, fish, mammal, something, something]

According to Rule 3, the duplicate something is removed from the chain. The final result is the complete inheritance chain for marine-mammal:
Figure 1 shows the complete inheritance hierarchy for Example 1. It is possible to write class definitions that cannot be ordered using the three rules. As an example, consider these class definitions:

\begin{verbatim}
(define-class A (:parents B C))
(define-class C (:parents B))
\end{verbatim}

From the definition of object C, we find that C must precede B because a class always precedes its superclasses, but B must precede C in order to preserve the local ordering of superclasses in the \texttt{parents} list of A. When an inheritance chain cannot be computed according to the three rules, ERIC signals an error and prints out information detailing which classes are in conflict.

The \texttt{:documentation} list is an optional string that is used to document the class being defined.

The optional \texttt{:instance-attributes} list declares what new attributes an instance of the defined class will have in addition to those it gets via inheritance. The \texttt{:instance-attributes} list is composed of zero or more attribute names or name-value pairs, where value is a lisp form that is evaluated at the time of definition to a default initial value. If a default value is not provided, its default is NIL. Attributes are inherited by first taking the union of the instance variables of each class in the inheritance chain and then eliminating duplicates. When eliminating duplicates, precedence is given to the leftmost
This diagram shows the inheritance hierarchy of Example 1. The class and instance variables inherited by each object is shown inside the object's box.

Figure 1
attribute with a default value. (Leftmost being with respect to
the inheritance chain.) In Example 1, an instance of marine-
mammal will have the following attributes: weight (with a
default value of 2-tons), genus, species, common-name, and
length (with a default value of long).

Class attributes are declared by an optional :class-
attributes list and are inherited in a way similar to instance
attributes. Class attributes belong only to class objects; they
are not inherited by instance objects. Class attributes can be
used to store any type of information, but are most useful for
storing information that is common to all members belonging to a
class and for managing instance objects and subclasses.

The value returned by the define-class form is the actual
class object being defined. This object is also bound to the
symbol in the name position of the define-class form. This
symbol is declared to be a global variable when the define-class
form is evaluated, so you can always use this symbol as a
"handle" to get ahold of the class object anywhere in your
programs. You should be careful not to rebind this symbol to
another value, or you may not be able to get ahold of the class
object again.

Class objects identify themselves when printed as:

#<CLASS x>

where x is the name of the class, as specified in the class'
define-class form. For example, the result of typing the form:
(eval marine-mammal) at the top-level of a lisp system after Example 1 has been evaluated will be the class object marine-mammal, which prints itself as:

#<CLASS MARINE-MAMMAL>

There is also a predicate function, class-object?, of one argument that will return true if an object is an ERIC class object.

Every class object in ERIC has several predefined attributes which may be inspected by users: documentation, the string which may have been included in the :documentation list of the class' define-class form; parents, the :parents list from the define-class form; offspring, a list of all the immediate subclasses and instances of this class; and status and schedule, whose functions will be explained in Chapter 4. The value of these attributes may be used in your programs, but you should never try to change their values. These attributes are established and maintained by ERIC; any modification by a user could (and probably will) cause problems in the evaluation of programs.
1.2 Instance Objects

Instances are the operational elements of an object-oriented simulation. It is the interaction of instance objects that simulates the interaction of real-world objects in a system. Instance objects can be created in two ways: sending a class a make instance message, or by using the function make-object.

There are two types of make instance messages: the first creates a named instance belonging to a specified class; the second is similar, but also allows the specification of attribute values. The first message is of the form

(ask class make instance x)

which results in the creation of a named instance of class that is bound to the symbol x. As was the case with class names, the symbol x is declared to be a global variable and should not be rebound or you may lose your handle on the object. To aid in identification, the print name of the object created is #<x>.

The second make instance message is of the form:

(ask class make instance x with (attribute value)*)

where attribute is an instance attribute of class and value is the value assigned to that attribute. For example,

(ask fish make instance george with
  genus betta
  species splendens
  common-name siamese-fighting-fish)
will return the object george, with print name #<GEORGE>. Any attributes that are not specified in the attribute-value portion of the message will take their normal default values. In this example, george will have a default length of NIL.

The function **make-object**, of the form

(make-object class &rest attributes)

creates an anonymous instance of type `class`. An anonymous instance does not have a name associated with it, is not bound to any symbol, and prints itself as

#<unnamed instance of class: N>

where `N` is a unique serial number which can be used to visually tell if two anonymous objects are the same. The &rest arguments must be keyword-value pairs that specify the initial value of instance attributes. A keyword is simply an attribute name prefixed by a colon. Thus,

(make-object fish
 :genus 'betta
 :species 'splendens
 :common-name 'siamese-fighting-fish)

will create an anonymous instance of fish with the same attribute values as george.

The single argument predicate **instance-object?** returns true if an object is an ERIC instance. Instance objects have three predefined attributes: parents, schedule, and status. Parents is a single element list pointing to the class of which the instance is a member.
2.0 Message Passing

Recall that objects have behaviors which can perform computations. Behaviors are pieces of procedural code, each of which is identified by a message, which is a sequence of symbols. Behaviors are invoked by a form of indirect function calling known as message passing. When an object is passed a message, the behavior identified by that message is executed.

A message is passed to an object with the ask function. Borrowing from the examples in Chapter 1, George's common name could be determined by sending this message:

(ask george recall your common-name)

to which george would reply siamese-fighting-fish. The general form of the ask function is:

(ask object message)

where object is either an ERIC class or instance object, and message is the sequence of symbols denoting the message being sent to the object.
2.1 Defining Behaviors

Suppose we would like to provide members of the class `fish` with a set of behaviors which might reflect how a fish actually lives and behaves. A behavior for perpetuating the species could be defined by:

```lisp
(ask fish when receiving (perpetuate the species)
  (ask myself find a fish of opposite sex)
  (ask myself perform courtship behaviors)
  (ask myself settle down and raise kids))
```

There are several important things to notice in this example.

First, we have just defined a behavior for members of the class `fish` that is associated with the message "perpetuate the species". Behaviors are defined by a message of the form:

```lisp
(ask class when receiving pattern {action})
```

where `pattern` is a list specifying the message name and `action` is zero or more lisp forms that are to be evaluated when the behavior is invoked.

Second, the use of 'myself' in the class position of the messages inside the behavior being defined requires an explanation. The variable `myself` has a special meaning in ERIC. Each time a message is passed, `myself` is bound to the object the message is being sent to. For example, during the evaluation of:

```lisp
(ask george perpetuate the species)
```

the variable `myself` will be bound to the instance object `george`. 

**Myself** allows the definition of behaviors that are applicable to any member of a class, without having to know the identity of the member.

Third, when a member of *fish* is sent this message, it will send out three more messages to itself: find a mate, perform courtship, and have children. The three messages sent out by our example must also have behaviors defined to handle them. **ERIC** behaviors are not limited to sending messages to *myself*. Inside a behavior you can send messages to any object, be it an instance or class.

[There is one other global variable in **ERIC** that has a special meaning: *message-sender*, which is bound to the object which sent the current message. If the message was not sent by an **ERIC** object, *message-sender* is bound to the symbol 'user'.]

### 2.2 Messages are Not Evaluated

**Ask** is a lisp macro which evaluates only its class argument; the message argument is not evaluated. If you wish to include forms that get evaluated in a message, you must mark the forms with **evaluation prefix characters**. These special characters tell **ERIC** that the form directly following them should be evaluated, and the result should be spliced into the message sequence.
There are two evaluation prefix characters in ERIC: the exclamation mark (!), and the ampersand (&). Both of these characters specify that the form immediately following them is to be evaluated, but the two characters differ in how they specify the result is to be spliced into the message sequence. The exclamation mark specifies that the result is to be spliced in "as is." The ampersand should only be used with forms that evaluate to a list; this list is then "unwrapped" and spliced into the message. Example 2 illustrates how the evaluation prefix characters work.

### 2.3 Messages are Actually Patterns

Behaviors which could respond to classes of messages would be more useful than behaviors that can only respond to just one specific message. Take as an example the "ask george recall your common-name" message. Without some way to define behaviors for classes of messages, it would be necessary to write a different

**Example 2**

**Ask Form Evaluation**

(ask thing go to !place)  ==>  (ask george go to tahiti)  
  thing = george  
  place = tahiti

(ask object go to &place)  ==>  (ask george go to the south sea isles)  
  object = george  
  place = (the south sea isles)

(ask mammal &(list 'growl) !(+ 1 2) times)  
  ==>  (ask mammal growl 3 times)
behavior for recalling every attribute an object has. This could be quite tedious. It is desirable to have a single behavior that would be responsible for handling all messages of the form "recall your \( x \)."

Writing behaviors that handle classes of messages is accomplished in ERIC by using pattern variables in the message pattern of a behavior definition. The actual definition of the behavior for recalling the value of an object's attribute is:

\[
\text{(ask something when receiving (recall your } \text{attribute) (object-get myself attribute))}
\]

\text{Attribute} is a pattern variable in this definition.

Pattern variables are denoted by the pattern matching prefix characters > and +. (The greater-than sign and the plus sign, respectively.) When used in a pattern, these prefix characters act as wildcards -- they match against anything. The > prefix will match single forms such as an atom or a parenthesized list. The + prefix will match any number of consecutive forms. If a symbol is prefixed by either of these characters in a pattern, the matcher will bind the symbol to the matched form. Example 3 gives some examples of how pattern matching prefix characters work. In this example, \text{attribute} is prefixed by the > character, so if a match occurs, \text{attribute} will be bound to the attribute whose value is being requested. Pattern variables perform the role of formal parameters for behaviors.
Pattern Datum Results

(a b c) (a b c) match, no bindings
(a b c) (a 1 c) no match
(a >b c) (a 1 c) match, b = 1
(a >b c) (a (1 2) c) match, b = (1 2)
(a > c) (a 1 c) match, no bindings
(a >b c) (a 1 2 c) no match
(a +b c) (a 1 2 c) match, b = (1 2)
(a >b c) (a c) no match
(a +b c) (a c) match, b = ()
(a +) (a 1 2 c) match, no bindings
(>a +b c >d) (e f c g) match, a = e,
               b = (f),
               d = g

Matching Prefix Characters
Example 3

2.4 Inheritance of Behaviors

Objects inherit behaviors from their superclasses, just like they inherit attributes. The mechanism is fairly simple and is based on an object's inheritance chain. When an object is sent a message, it looks to its parent classes for a behavior with a pattern that matches the message. Each superclass on the inheritance chain is checked, from left to right, until a matching behavior is found. If no suitable behavior is found, ERIC signals an error.

Going back to the objects defined in Example 1, let's evaluate the following behavior definitions:

(ask something when receiving (move)
 (print 'moving))
(ask fish when receiving (move)
  (print 'swimming))

(ask mammal when receiving (move)
  (print 'walking))

After evaluation, something, fish, and mammal will all have a pattern-action pair for the message "move" in their repertoire of behaviors. If we now evaluate:

(ask george move)

the result is that 'swimming' is printed. George looked to its parent, fish, for a matching behavior, found it, and evaluated it. If we ask fish or mammal to move, the result is that 'moving' is printed. You might have expected fish to print 'swimming' and mammal to print 'walking', but remember: an object looks to its parent classes for its behaviors. The parent class for both fish and mammal is something, so something's move behavior is evaluated. If we ask marine-mammal to move, 'swimming' is printed.

It may seem strange that a class object doesn't look to itself for a matching behavior, but there is a simple reason why it doesn't. In ERIC, a class defines a set of objects -- it is not a member of that set. A class object is a member of its parent classes, so that is where it should look for its behaviors. Because all objects search for behaviors by looking to their parents, both instance objects and class objects have the same behavior inheritance mechanisms and act in a uniform manner.
2.5 Before and After Daemons

A daemon is a piece of code that is automatically invoked when some specified event occurs. In ERIC there are two kinds of daemons: before daemons, which are evaluated before a specific message is handled; and after daemons, which are evaluated after a specific message has been handled.

Daemons are useful in a variety of ways; two examples of which will now be given. Often a behavior is defined for a given class, say x. Each of the subclasses of x would like to use this behavior, but a few of the subclasses need to perform different preparatory actions before this behavior is evaluated. Each subclass of x that needs to perform preparatory actions can define a before daemon to do them. Daemons are also useful for uncoupling I/O functions, such as graphics, from behavior definitions. Because the I/O is separated from behaviors, it is easy to run simulations with or without graphics and to convert simulations to work with a different I/O device.

Daemons are defined in a way similar to behaviors. Before daemons are defined by a message of the form:

(ask class before receiving pattern (action*))

and after daemons are defined by the message:

(ask class after receiving pattern (action*))

A class can have only one before and one after daemon for each
message pattern. It is not necessary for a class to have a behavior that handles this message, as long as one of its superclasses does.

The model for ERIC's message handling mechanism developed in Section 2.4 must now be modified to include daemons. When an object is sent a message, the parent classes on the object's inheritance chain are searched from left to right for before daemons that match the message. If a matching before daemon is found, it is evaluated and the search continues with the next class in the chain until all the superclasses on the inheritance chain have been searched. Then a search is made for the behavior which will handle the message (henceforth also called the primary behavior), which is made according to the description given in Section 2.4. After the proper behavior has been evaluated, the parent classes on the object's inheritance chain are searched from right to left for after daemons that match the message. If a matching after daemon is found, it is evaluated and the search continues with the next class in the chain until all the superclasses on the inheritance chain have been searched.

Note that all the before and after daemons defined along an object's inheritance chain for a given behavior are executed, and that after daemons are executed in the reverse order of before daemons. Imagine that the inheritance chain is a path you are walking along. You start at the beginning of the path (the left end of the chain) and walk to the end of the path (the right end
of the chain), stopping along the way to evaluate any appropriate before daemons you find. While you search for appropriate before daemons, you also look for the correct behavior to handle the message. When you come to the end of the path, you evaluate the behavior you found, and turn around to walk back to the beginning of the path. As you walk back, you evaluate any appropriate after daemons you find as you come across them. Once you reach the beginning of the path again, your journey is finished.

An example of daemon inheritance is in order. Continuing in the spirit of Example 1, suppose the following forms are evaluated:

```
(ask fish before receiving (move)
  (print 'before-fish-move))

(ask fish after receiving (move)
  (print 'after-fish-move))

(ask mammal before receiving (move)
  (print 'before-mammal-move))

(ask mammal after receiving (move)
  (print 'after-mammal-move))

(ask marine-mammal before receiving (move)
  (print 'before-marine-mammal-move))

(ask marine-mammal after receiving (move)
  (print 'after-marine-mammal-move))
```

If you now send `george` a message to move, the following would be printed:

```
before-fish-move
swimming
after-fish-move
```
A more complex example would be to send an instance of marine-mammal a move message, which would result in this being printed:

before-marine-mammal-move
before-fish-move
before-mammal-move
swimming
after-mammal-move
after-fish-move
after-marine-mammal-move

Daemons do not return any values. They are useful for side-effect only. The value returned by a message pass is the value returned by the behavior which handled the message, regardless of any daemons that may have been evaluated. Daemons may use parameter values that are accessible via pattern variables used in the pattern part of their defining message.

2.6 Wrappers

The final behavioral concept in ERIC that will be discussed is the wrapper. Daemons let you put code before and after the execution of a behavior; wrappers allow you to put code around the execution of a superclass' behavior. Wrappers are not a distinct class of procedural entities like before and after daemons are; instead, they are primary behaviors that use the continue-passing macro to continue searching the inheritance chain for message handlers.
The `continue-passing` macro can be called either with no arguments or with one argument. In the no argument case, `continue-passing` allows the behavior currently handling a message to execute the next behavior along the inheritance chain capable of handling the same message. Consider the following simple example, based on the objects defined in Example 1. Several new behaviors are added by sending the following messages:

```lisp
(ask something when receiving (print >n)
 (print 'something)
 (princ n))

(ask fish when receiving (print >n)
 (print 'fish)
 (princ n)
 (continue-passing))

(ask mammal when receiving (print >n)
 (print 'mammal)
 (princ n))
```

After defining these new behaviors, we send `george` a message to print the number 5:

```lisp
(ask george print 5)
```

and the resulting output is:

```
fish 5
something 5
```

The "print 5" message was first handled by fish's "print >n" behavior, which printed the first line of output, and then the call to `continue-passing` sends the "print 5" message on up the inheritance chain to something, which then prints the second line of output. Similarly, if the same message is sent to marine-mammal:
(ask marine-mammal print 5)

the resulting output is:

fish 5
mammal 5

because after fish, the next superclass on marine-mammal's inheritance chain that has a handler for the "print 5" message is mammal.

The message sent up the inheritance chain by a wrapper can be altered by including a new message as an argument to **continue-passing**. If we redefine fish's print behavior to be:

(ask fish when receiving (print >n)
  (print 'fish)
  (princ n)
  (continue-passing (print !(- n 1)))))

and send the message:

(ask george print 5)

the result now is:

fish 5
something 4

Note that the print message was changed by calling the **continue-passing** macro with the new message to be sent up the inheritance chain as its argument.

**Continue-passing** is a powerful mechanism for side-stepping normal message handling in ERIC. The new message passed up the inheritance chain can be anything you desire; it is not limited to being a variant of the original message. You should use this
mechanism with discretion, however, because its run-time behavior may be difficult to comprehend by just looking at the code. Note that you can only use *continue-passing* at most once in a behavior. It will not work correctly if you try to use it twice.
3.0 Behaviors Defined for Something

This chapter describes the predefined behaviors in ERIC. These behaviors have been defined for the object something, so every new object you define will inherit these behaviors.

3.1 Making Instance Objects

mak_instance >ob

Creates a named instance object of the class that was sent the message. The instance is bound to the symbol specified by ob. See Section 1.2 for more information. Applicable only to class objects; instance objects will signal an error.

mak_instance >ob with +attributes

Does everything the previous message does, but allows you to assign initial values to the newly created instance's attributes. Attributes is one or more attribute-value pairs. See Section 1.2 for more details and an example. Applicable only to class objects; instance objects will signal an error.
If \( ob \) already exists as an instance object when either of these messages are sent, the old \( ob \) is "erased," in the sense that it is removed from its parent's list of offspring and its \textit{schedule} is set to NIL (see Chapter 4 for the significance of this action). However, the old \( ob \) does still exist somewhere in the lisp environment, so that any pointers you had to it will still be intact. If \( ob \) already exists as a class object when either of these messages are sent, an error is signalled.

After an instance is created, it is sent an "initialize yourself" message. The default behavior for this message does nothing.

3.2 Defining Behaviors and Daemons

\begin{verbatim}
when receiving \texttt{>pattern +actions}
before receiving \texttt{>pattern +actions}
after receiving \texttt{>pattern +actions}
\end{verbatim}

These messages allow you to define primary behaviors, before daemons, and after daemons that are local to the class object receiving them. \texttt{Pattern} is the message template that will be associated with the \texttt{actions} code. See Section 2.1 for more details and an example. Applicable only to class objects; instance objects will signal an error.
forget your local behaviors matching >pattern
forget your local before daemons matching >pattern
forget your local after daemons matching >pattern

These messages allow you to delete local primary behaviors, before daemons, and after daemons whose invoking message matches pattern. These behaviors return an integer telling the number of behaviors that were deleted. Applicable only to class objects; instance objects will signal an error.

3.3 Print Functions

One of the most important ways an object can interact with the user is to display information about its current state. There are several messages for telling an object to print various information.

print yourself

The object will display all of its attributes and values. You get a look at the data structure representing the object. For class objects, this includes the object's behaviors, daemons, immediate descendants, and immediate parents.

print your attributes

The object will display all of the class or instance attributes that were declared in the object's definition. This
message is useful when you are only interested in seeing the attributes you gave the object, and don't care about the system defined attributes. The information printed by this message is less cluttered than that printed by the previous message.

print your >attribute

Prints the value of the attribute specified by the parameter attribute.

print your local messages

Prints the local behaviors and daemons defined on this object, in alphabetical order. If the object is a class, the behaviors and daemons that have been defined on the class are printed; if the object is an instance, the behaviors and daemons defined on its parent class are printed.

print your messages

Similar to the previous message, but prints every message an object has a handler for. This includes behaviors and daemons that have been defined for an object and all those it inherits from its superclasses, except for the primary behaviors inherited from the superclass something. Something has so many behaviors that they clutter the screen and obscure the behaviors you have defined.
print your messages matching >pattern

Prints all of the object's behaviors and daemons capable of handling messages matching pattern. Pattern is a list which may contain wildcards as described in Chapter 2. For example, to see all the messages something can respond to that begin with the symbol print, you would send the message:

(ask something print your messages matching (print +))

3.4 Recalling the Value of Attributes

Printing the values of attributes is nice for human-object interaction, but not very useful for object-object interaction. These recall behaviors return values that can be used in programs.

recall your >attribute

Returns the value of the attribute specified by the attribute parameter.

recall the >attribute for your class

Returns the value for a class attribute, specified by the attribute parameter, of a class to which the object is a member. If the object sent the message is an instance, the class attribute will belong to its parent class. If the object is a
class object, the attribute value returned will be from the first superclass on the object's parent list that has this attribute. If attribute cannot be found for a class, an error is signalled.

recall your local messages

Returns a list of the local behaviors and daemons defined on the object. If the object is a class, the behaviors defined on this class are returned; if the object is an instance, the behaviors defined on its parent class are returned.

recall your messages

Returns a list of all the behaviors and daemons that are available to the object, including those which it has inherited from its superclasses.

recall your messages matching \texttt{\textgreater pattern}

Returns a list of all the behaviors and daemons available to the object that handle messages matching \texttt{pattern}.

recall your descendants

Returns a list of all the descendants of a class. Descendants are defined to be instances and all subclasses and their instances. Applicable only to class objects; instance objects will signal an error.
**recall your instances**

Returns a list of all the instances belonging to this class or one of its subclasses. Applicable only to class objects; instance objects will signal an error.

**recall your subclasses**

Returns a list of all the subclasses of the object. Applicable only to class objects; instance objects will signal an error.

**recall your superclasses**

Returns a list of all the superclasses of an object.

3.5 Setting Attribute Values

**set your >attribute to >value**

This behavior is for assigning a value to an attribute. This works for both instance attributes and class attributes. If the object does not have *attribute* as one of its defined attributes, an error is signalled.
set the >attribute for your class to >value

Assigns value to the class attribute specified by attribute. Applicable only to instance objects; if this message is sent to a class object, an error will be signalled. If the object's class does not have attribute as one of its defined class attributes, an error is signalled.

3.6 Sending Messages to Attributes

to ask each of your >attribute to +action

Sends the message action to each element in the value of the attribute specified by attribute. The attribute's value should be a list. For example, to have each object in the offspring attribute of something print itself, you would send this message:

(ask something to ask each of your offspring to print your self)

to ask your >attribute to +action

Sends the message action to the object that is the value of the attribute specified by attribute.
3.7 Tracing and Recording Messages

ERIC provides two ways to observe the passing of messages: tracing and recording. Each of these facilities serves a different purpose. The trace facility is useful for debugging programs and is similar to lisp tracing facilities; the recorder saves a record of messages passed for later examination.

trace your messages matching >pattern

This behavior marks all of the class object's primary behaviors which match pattern for tracing. Pattern may contain wildcard matching characters. When any object that is a member of this class receives messages which match pattern, the trace facility prints four pieces of information to the current standard output stream: the current trace depth, the class that is handling the message, the message itself, and the value returned by the invoked behavior. The trace facility indents nested message passes. This behavior is applicable only to class objects; if sent to an instance object, an error will be signalled.

untrace your messages matching >pattern

This behavior unmarks all of the class object's primary behaviors whose invoking message matches pattern so they will not
be traced. This behavior is applicable only to class objects; if sent to an instance object, an error will be signalled.

```
record your messages matching >pattern to >stream
unrecord your messages matching >pattern
```

The recording facility is similar to the trace facility, except that there is no indentation and only the message passes are recorded, not their results. The current simulation time and the object who sent the message are also included with each message record. Stream must already be open for output, and you must close it when you are finished recording.
Chapter 4
Event Scheduling

4.0 The CLOCK

The features of ERIC described so far have only dealt with its object-oriented programming capabilities. Objects alone do not a simulation make. There must also be a temporal control mechanism which allows objects to interact over time. In ERIC this mechanism is the clock object. The clock controls the flow of time in the simulation and also allows actions to be scheduled for execution in the future. The clock is an instance object of class simulation-clock, and has three instance attributes: \textit{simtime}, \textit{event-list}, and \textit{ticksize}.

\textit{Simtime} is the current time in the simulation. In ERIC time is represented as a real number which has no built-in scale of measure. It is left to the programmer to decide what scale of measure (if any) is associated with time, and to use this scale consistently within all object behaviors. For example, if you wish time to be measured in seconds, you should write behaviors that consistently refer to time in terms of seconds. Because time is represented as a real number, there is no indivisible interval of time in ERIC.
Simulations generally keep actions scheduled to happen in the future in some sort of time-ordered queue. In ERIC, this queue is maintained as the clock's event-list. The clock moves the simulation forward in time by executing events in the queue. The progression of simulation time is not smooth and continuous -- it jumps from one event to the next. The interval of time between events never really exists.

It is often convenient to stop the execution of a simulation at regular intervals, or to run a simulation for a specified period of time. The clock will start the execution of a simulation when it receives a tick message:

(ask clock tick)

The simulation will then run for a length of time specified by the clock's ticksize attribute, which controls how many time units pass during each tick of the clock. Changing the value of ticksize is one way you can control how long a simulation runs. Another way is to use the message:

(ask clock tick >n times)

which is simply a loop which sends clock a tick message n times.

The "ideal" value of ticksize varies from simulation to simulation. Bear in mind that the value of ticksize has no direct effect on the behavior of the simulation; the clock's ticking is only for interaction and control purposes. Generally, the tick size should be longer than the mean time between events.
in a simulation. There is not much purpose in stopping every second of simulation time if the mean time between events is several minutes of simulation time.

4.1 Scheduling Events

There are two basic messages for scheduling actions to happen at some future time:

(ask clock to schedule >object to +action at time >x)

(ask clock to schedule >object to +action in >x time units)

The first message schedules an action to happen at some absolute time; the second message schedules an action to happen relative to the time at which the message was sent. Action must be a message that object can handle, or there will be an error signalled at some point in the future when the object tries to execute the action.

A small example of scheduling is in order. Suppose we want a behavior that makes a member of the fish class move every 10 seconds. Notice that time was referred to in terms of seconds; you can assign any scale of measure to simulated time by simply deciding to use that scale consistently throughout your simulation code. To make the use of seconds explicit, a new scheduling behavior for clock is written:

(ask clock when receiving (to schedule >object to +action in >x seconds)

(ask clock to schedule !object to &action in !x time units))
In a similar way, you can define behaviors for dealing with time in whatever scale of measure you like. Now we can write the new behavior for fish, which will be invoked by the message "move around":

(ask fish when receiving (move around)
   (ask myself move)
   (ask clock to schedule !myself to move around in 10 seconds))

This behavior first tells the object send the message to move, and then schedules the object to move around again in ten seconds. We could set george, the fish created in Chapter 1, in motion by sending it the message "move around" and then asking clock to tick a few times. Every ten seconds george would move and then reschedule himself to move around in another ten seconds.

4.2 The Queueing Mechanism in More Detail

There is more to the event queueing mechanism than was described in Section 4.0. A thorough grasp of this mechanism is central to understanding how ERIC works. ERIC's scheduler is a bit unusual in that the event queue is distributed between the clock and the other objects in the simulation.
Studies have shown that simulations spend a large percentage of their run time managing their event queue. Therefore, it is essential that a simulation language provides an efficient queueing mechanism. Managing the event queue mostly consists of two operations: inserting new events into the proper place in the ordered queue, and retrieving the event which should be executed next. Since the queue is time-ordered, the retrieval operation is trivial. Insertion is much more expensive than deletion, with the cost of inserting an event depending on how large the queue is. It is also expensive to delete an event from the queue. However, in most simulations this is a rare operation, and some simulation languages do not support event deletion. Like insertion, the cost of a deletion depends on the event queue's size.

ERIC was designed to support simulations which are composed of intelligent objects. One of the things intelligent objects in the real world do a lot of is build, execute, and modify plans; it is reasonable to assume that intelligent objects in a simulation would need to do the same. Therefore, ERIC should make it easy and efficient for objects to examine and modify their scheduled future events. That means providing an efficient way to search for, insert, and delete events in the event queue. This is where ERIC's distributed queueing mechanism comes in.

As mentioned earlier, the length of the event queue is an important factor in how long it takes to perform search, insert, and delete operations. Therefore, it is desirable to keep the
event queue as small as possible. The first part of ERIC's queue mechanism, the clock's event-list attribute, keeps track of which objects have actions scheduled and when the actions are to be executed. Actually, the event-list only keeps pointers to a small number of the (possibly many) events scheduled for a given object. Ideally the event-list will contain only one reference to a given object, but this is not always possible. Keeping only a few pointers to each object helps reduce the size of the event-list.

Each object's schedule attribute contains information about its scheduled future actions. Schedule stores a time ordered list of data structures called plans, which contain three pieces of information: what action is to be performed, when the action is to be performed, and who scheduled the action. Allowing each object to store its own plans facilitates the examination and modification of plans. It is far more efficient to have an object rummage through its schedule attribute, which contains only its own scheduled future actions, than to have it rummage through a monolithic event queue that contains every object's future actions.

When an action is scheduled for the object $X$, the clock checks $X$'s schedule for plans. If $X$ currently has no plans in its schedule, or if the new action is supposed to happen before any event currently in the schedule, the clock places a reference to $X$'s future action in event-list. If $X$ currently has actions
scheduled to happen before the new action, then there already is
an appropriate reference to X in the event-list, so a new
reference is not inserted. (This is how the event-list size is
kept down to about one reference per object.) In either case,
the future action is inserted into the object's schedule.

When the clock pulls an event off the event-list for
execution, it checks the schedule of the object specified in the
event to see if the object has a plan that should be executed at
the current time. If so, it is executed; if not, nothing
happens. In either case, the clock then puts a reference to the
object's next scheduled action into the event-list. The cost of
checking an object's schedule when there is nothing to do is less
expensive than trying to delete an action from the event queue.
This allows plans to be deleted or modified efficiently.

4.3 Objects Can Die

Another benefit of the distributed event queue is that it is
easy to "kill" an object. In the physical world, objects can be
destroyed and are no longer able to perform actions. All
instance objects in ERIC have a status attribute which is either
the symbol 'alive' or 'dead'. An instance object can be killed
by sending it the message:

(ask object kill yourself)
Unlike most dead objects in the physical world, dead ERIC objects still exist and are able to respond to messages sent to them. However, they cannot be scheduled to perform any actions in the future and they will not perform any actions that had been scheduled prior to their death. If you try to schedule an action for a dead object, an error will be signalled. It may be necessary in your application to perform certain actions when an object dies; remember that you can use daemons or wrappers for this.

Two lisp predicate functions, live-object? and dead-object?, tell you if an object is alive or dead, respectively. You should avoid modifying the status attribute in your own code. If you need to keep information about an object's "status" with respect to your application, use an instance attribute of your own making.

4.4 Plan Manipulation

As mentioned earlier, the future scheduled actions for an object are stored in the object's schedule attribute in the form of plans. Each plan is a data structure which holds three pieces of information: the action to be performed, the time when the action should be performed, and who scheduled the action. These pieces of information can be retrieved from a plan with the
functions `get-plan-action`, `get-plan-time`, and `get-plan-scheduler`, respectively. Each of these functions takes a plan as their sole argument.

Several behaviors are provided that allow you to manipulate an object's schedule. They are:

- **forget your plans matching `pattern`**

  Removes all of an object's plans whose action matches `pattern` from schedule. The matching plans will not get executed. `Pattern` may include any number of wildcard pattern variables.

- **forget your plans at time `>x`**

  Forgets all of an object's plans that are scheduled to happen at time `x`. These plans will not get executed.

- **forget your plans before time `>x`**

  Forgets all of an object's plans that are scheduled to happen before (but not including) time `x`. These plans will not get executed.

- **forget your plans after time `>x`**

  Forgets all of an object's plans that are scheduled to happen after (but not including) time `x`. These plans will not get executed.
**forget your plans between times \texttt{time1} and \texttt{time2}**

Forgets all of an object's plans that are scheduled to happen between times \texttt{time1} and \texttt{time2}, inclusive. These plans will not get executed.

If these behaviors do not satisfy the needs of your application, you can write your own. You are allowed only to remove plans from an object's \texttt{schedule}; if you wish to add them, you must send scheduling messages to the clock. \texttt{Schedule} contains a list of plans, ordered from the earliest to latest time of scheduled execution. Remember to maintain this ordering when you modify \texttt{schedule}, or things will go awry.
Chapter 5
Miscellaneous Matters

5.0 Purpose

The purpose of this chapter is to present several important short topics that do not fall neatly into the previous chapters. Most of these topics deal with lisp functions that are useful for programming in ERIC.

5.1 Objects are Structures

ERIC objects are implemented as CommonLisp structures. Any of the facilities provided by CommonLisp for dealing with objects may be used with ERIC objects. The typing system is of particular importance. All class objects in ERIC are structures of the type 'class-object'. Instance objects are also structures, but they may come in a variety of types.

When a class is created via define-object, ERIC builds a CommonLisp defstruct form appropriate for implementing instance objects of that class. One of the many things this defstruct form does is create a new lisp data type with the same name as
the ERIC class name. This name can be used with the CommonLisp function \texttt{typep} and \texttt{type-of}, so that

\begin{verbatim}
(typep george 'fish)
\end{verbatim}

is true and

\begin{verbatim}
(type-of george)
\end{verbatim}

returns 'fish'.

The defstruct also defines accessor functions for each of an object's instance attributes. (See the CommonLisp language definition for more information on defstruct.) Accessor functions perform the same job as the "recall your >attribute" and "set your >attribute to >value" messages, but accessor functions are much more efficient. However, accessor functions are suitable only in special situations and should be used with extreme care. The reason for this lies in CommonLisp's limited inheritance mechanism for structures.

CommonLisp's structure facility is not designed to support multiple inheritance of attributes. Therefore, ERIC has to map a class' attributes (some of which may be inherited from multiple superclasses) onto structures. This mapping is not used by the accessor functions generated automatically by a defstruct, so the accessors don't always behave correctly. The only situation where it is safe to use defstruct-generated accessor function for a given instance attribute is when the class the attribute belongs to will never be combined with another class that has an instance attribute of the same name.
Message passing is a lot more expensive than normal function calling. Therefore, the two messages for accessing object attributes can exact quite a toll on a simulation’s run-time performance. Never fear, for ERIC provides two lisp functions that will correctly access any object's attributes (be the object a class or an instance) more efficiently than the messages can. The functions are \texttt{object-get} and \texttt{object-put}, and they are of the form:

\begin{align*}
\text{(object-get object attribute)} \\
\text{(object-put object attribute value)}
\end{align*}

Using these functions to access attributes will enhance run-time performance, but you lose the flexibility of message passing. You will not be able to take advantage of the daemon, tracing, or recording facilities ERIC provides. You should consider all these factors when deciding which accessing method to use.

5.2 Some Useful Predicates

This section presents some useful lisp predicate functions. They have been presented separately elsewhere in this paper, but are gathered here for convenience. All of the predicates take a single argument.

\texttt{object?}  Returns true if the argument is an ERIC object.
class-object? Returns true if the argument is an ERIC class object, nil otherwise.

instance-object? Returns true if the argument is an ERIC instance object, nil otherwise.

live-object? Returns true if the argument is a live ERIC object, nil otherwise.

dead-object? Returns true if the argument is a dead ERIC object, nil otherwise.

5.3 Matching Facility

The pattern matching facility of ERIC is available for you to use via the ematch function, of the form:

(ematch pattern datum)

which matches the datum against the pattern. Pattern may contain pattern variables and wildcards. There are two caveats when pattern matching: the same pattern variable should not appear twice in the same pattern; and pattern variables should not appear immediately after a + or +var wildcard.

The result returned by ematch is one of three possibilities: NIL, if there is no match; T, if the match is successful but there are no variables in the pattern; or an association list of variables and bindings, if the match is successful and there are variables in pattern.

MISSION
of
Rome Air Development Center

RADC plans and executes research, development, test
and selected acquisition programs in support of
Command, Control, Communications and Intelligence
(C3I) activities. Technical and engineering
support within areas of competence is provided to
ESD Program Offices (POs) and other ESD elements
to perform effective acquisition of C3I systems.
The areas of technical competence include
communications, command and control, battle
management, information processing, surveillance
sensors, intelligence data collection and handing,
solid state sciences, electromagnetics, and
propagation, and electronic, maintainability,
and compatibility.
