We investigated the alterations of rat aortic alpha₁-adrenoceptors and alpha₁-adrenergic stimulated phosphoinositide (PI) metabolism in intraperitoneal sepsis. An analysis of [125I]-hydroxethylaminotetralone (HEAT) binding to alpha₁-adrenoceptors on rat aortic membranes revealed decreased numbers of receptors without changes in affinity. The maximum number of binding sites decreased from 349 ± 35 fmol/mg to 146 ± 16 fmol/mg (P < 0.05 vs. control). PI metabolism was similarly attenuated in aortae from septic rats. The norepinephrine-stimulated hydrolysis of [32P]-phosphatidylinositol-4,5-bisphosphate was significantly decreased in aortae from septic rats as was the alpha₁-adrenoceptor stimulated accumulation of [3H]-inositol monophosphate. Finally, the basal labeling of [32P]-phosphatidylinositol-4,5-bisphosphate but not of [32P]-phosphatidylinositol or [32P]-phosphatidic acid was significantly diminished.

These results imply that signal transduction induced by alpha₁-adrenoceptor agonists in rat aorta is significantly altered in intraperitoneal sepsis. These findings may help define the mechanisms of depressed aortic contractility in models of sepsis and endotoxic shock.

Key words: septic shock, phosphoinositide metabolism, vascular contraction, vasoconstriction, signal transduction

INTRODUCTION

Sepsis and septic shock are major causes of death in the United States among critically ill patients. Despite sophisticated and aggressive surgical and medical
interventions, the mortality rate in septic shock remains between 40 and 60% [1]. In
dissecting the pathophysiology of sepsis and endotoxemia, numerous investigators
have noted diminished peripheral vascular responsiveness to norepinephrine in both
humans [2] and in animal models of sepsis and endotoxemia [3,4]. Furthermore, an
attenuated response to exogenously applied norepinephrine (NE) has been noted in
isolated aorta by several groups of investigators [5,6] using a variety of models of
sepsis and endotoxemia. The mechanism of this phenomenon remains unknown [see
refs. 3,4 for review], but could reside in part in the signal transduction apparatus.

We recently found that NE-induced contraction of rat aorta, which is mediated
by alpha-adrenoceptors, appears to correlate with the breakdown of phosphoinosi-
tides (PI) [7]. Our original observations have now been replicated [8]. We also noted
that the potent vasoconstrictor 5-hydroxytryptamine [9] and several vasoactive prosta-
taglandins [10] also appear to induce rat aortic contraction, at least in part, via PI
breakdown [for review see refs. 3,4]. According to this scheme, following binding of
a ligand to the receptor a phosphoinositide-specific phospholipase C is activated
which cleaves phosphatidylinositol-4,5-bisphosphate to release inositol-triphosphate
(IP$_3$) as well as diacylglycerol (DAG). It is proposed that IP$_3$ mobilizes intracellular
calcium [11-15] while DAG activates protein kinase C. Phorbol esters, which mimic
the effects of endogenous DAG, are potent inducers of rat aortic contraction. Phorbol
esters induce vasoconstriction in part by the mobilization of extracellular calcium in
a nifedipine-sensitive fashion [16].

We previously discovered that hepatic alpha-adrenoceptors [17], as well as
vasopressin receptors [18], were decreased in intraperitoneal sepsis as well as in
chronic endotoxin infusion models of sepsis [19]. Spitzer and colleagues [20] found
that the alpha-adrenoceptors and vasopressin receptor-mediated mobilization of intracel-
lar calcium and activation of phosphoinositide hydrolysis were altered in intra-
peritoneal sepsis and in endotoxemia. These findings suggested to us that vascular PI
metabolism and adrenoceptors might be similarly altered in intraperitoneal sepsis.

In this paper we report significant alterations in aortic PI metabolism in rat
intraperitoneal sepsis. We also discovered diminution of aortic alpha-adrenoceptors.
These results suggest that experimental sepsis in the rat induces alterations in recep-
tor-coupled signal transduction in the aorta.

MATERIALS AND METHODS

Animals and Their Treatment

Sprague-Dawley rats (Taconic Farms, Baltimore, MD) weighing 200-350 g
were used in all experiments. Cecal ligation with two-hole puncture (CLP) was
performed as previously detailed [17]. The sham procedure was identical except that
the cecum was not devascularized, ligated or punctured. At 18-24 hr post-procedure,
surviving animals (60-70% survival at this time point) were sacrificed by decapita-
tion. Surviving animals displayed the signs of sepsis described by Wichterman et al.
[21] including piloerection, a bloody discharge from the nose and mucous mem-
branes, bloody diarrhea and lethargy.

Phosphoinositide Metabolism

PI turnover in the rat aorta measuring [3H]-inositol monophosphate accumulation
in the presence of 10 mM LiCl was determined by a modification of the
procedures of Berridge et al. [22] as previously described [7,9,23,24] using [3H]-
myo-inositol (16 Ci/mmole, New England Nuclear, Boston, MA). We previously
showed that this procedure accurately separates inositol mono-, bis- and tris-
phosphates.

For measurement of [32P]-phosphoinositide metabolism, rat aortic rings (4 mm
length) were prepared [10] and pre-incubated for 15 min in an oxygenated Hepes
buffer of the following composition (in mM) at 37°C: 140 NaCl, 10 D-glucose, 5
Hepes, 1.0 MgCl2, 1.5 CaCl2 pH-7.4. The segments were then incubated in [32P]-
orthophosphate (carrier free, Amersham) containing Hepes buffer (30μ Ci/ml) for 30
min to label phosphoinositide pools. Preliminary experiments disclosed steady-state
labeling of PI pools by this time period. Test agents were then added for various
periods of time and the reaction terminated by the addition of 0.9 ml chloroform/
methanol/HCl (100:200:0.1) solution followed by the addition of 0.3 ml water and
0.3 ml chloroform. Following lipid extraction, the lower phase was removed, washed
twice with upper phase and concentrated in a Speed-Vac. The samples were then
applied to oxalate pre-coated high performance thin layer chromatography plates
(HPTLC) prepared and run according to Jolles et al. [25]. [32P]-phosphoinositides
were identified by autoradiography with Kodak X-OMAT film (XAR-2) and by
authentic standards (Sigma Chemical Co., St. Louis, MO). The spots so identified
were scraped into scintillation vials and quantified by liquid scintillation spectrometry.

**Alpha1-Adrenoceptor Measurements in Rat Aorta**

Aortas from 12 rats (sham or CLP) were homogenized in 20 mM Tris-Cl buffer
(pH-7.40, 25°C) with a polytron homogenizer and then rehomogenized with a tightly-
fitting glass-glass homogenizer. This homogenate was centrifuged at 1,000 x g for
15 min (4°C) to sediment cellular debris and then a crude plasma membrane fraction
was prepared by centrifugation at 35,000 x g for 45 min. The resulting pellet was
resuspended in binding buffer [17] and incubated (0.5 ml t.v.) at 25°C for 60 min in
the presence of increasing doses of the selective alpha1-agonist [125I]-hydroxymethylam-
otetetralone (HEAT) (2,200 Ci/mmole, New England Nuclear, Boston, MA) in the
presence and absence of 1μM prazosin to determine specific binding. Membranes
were harvested by filtration on GF/B filters (Whatman) and washed by three 5-ml
washes of ice-cold binding buffer. Filters were placed into vials and counted in a
gamma counter.

Binding data were analyzed and binding parameters (Kd, Bmax) determined
using the nonlinear least-squares computerized curve fitting program (LIGAND) as
previously detailed [26] using the NIH DEC/10 computer. This iterative procedure
constructs models of binding according to the law of mass action for the interaction
of multiple ligands with multiple binding sites. The results of three or more exper-
iments were averaged to provide a weighted mean and SEM. Protein concentration
was determined as described by Bradford [27].

**Materials**

Solvents were of reagent grade or better (Fisher Chemical Co., St. Louis, MO); all other materials, unless otherwise specified, were from Sigma Chemical Co. (St.
Louis, MO).
RESULTS

Alterations in Rat Aortic PI Metabolism

Recent findings [20] have suggested that alterations might exist in hepatic PI metabolism in various sepsis and endotoxin models. We wished to determine whether similar changes might occur in aorta. Figure 1 shows that the NE-activated PI hydrolysis, as measured by the accumulation of [3H]-inositol monophosphate, (PI) was significantly attenuated in the aortas from septic rats, when compared with sham-operated controls. Dose-response studies for a short time of incubation have disclosed an EC_{50} of 0.93 ± 0.6 μM for NE-induced [3H]-IP accumulation [see ref. 21]; prazosin, a selective alpha1-antagonist inhibits the response with an IC_{50} of 3nM, while yohimbine (an alpha2-antagonist) has an IC_{50} of 100 nM [7]. Thus, the measurement of NE-induced [3H]-IP accumulation in rat aorta accurately reflects the activity of alpha1-adrenoreceptors.

Since phosphatidylinositol-4,5-bisphosphate (PIP\textsubscript{2}) is thought to be the primary substrate for PI hydrolysis in rat aorta [28], we sought to measure the accumulation of [3H]-inositol triphosphate (IP\textsubscript{3}) using our previously described technique. Because of the very small amounts of IP\textsubscript{3} released which are not degraded into IP we were unable to measure this metabolite (not shown). We were, however, able to measure the NE-stimulated breakdown of [32P]-phosphatidylinositol-4,5-bisphosphate. After a 30 sec exposure to 10 μM NE, [32P]-PIP\textsubscript{2} levels were decreased in aortas from sham-operated rats, but unchanged in aortas from septic rats (Table I). After a 1 min exposure to 10 μM NE [32P]-PIP\textsubscript{2} levels returned to baseline (Table II). This effect is similar to that reported by Rapoport in rat aorta [29].

Because the basal levels of [32P]-PIP\textsubscript{2} as well as basal [3H]-IP accumulation were diminished, we sought to determine whether these alterations represented generalized changes in PI synthesis. Accordingly, we measured the labeling of various PI metabolites in aortas from septic and sham-operated rats (Table II) in the basal state.

**Alpha₁-Adrenoceptor Alterations in Sepsis**

As is seen (Fig. 2) there was apparently a selective decrease in [³²P]-PIP₂ labeling in aortas from septic rats, without changes in the basal levels of [P]-PIP, [³²P]-PI or [³²P]-PA. Since PIP₂ has recently been shown to be the preferential substrate for the guanine nucleotide activated phospholipase C in rat aorta [28], this decreased substrate availability could account, in part, for the observed decrease in [³H]-IP accumulation. It does not account for the diminished [³²P]-PIP₂ breakdown. These results suggested to us that earlier events in the signal transduction pathway for aortic alpha₁-adrenoceptors might be perturbed in intraperitoneal sepsis.

Since we had previously found changes in hepatic alpha₁-adrenoceptors, it was reasonable to suggest that aortic receptors might be similarly altered. Figure 3 shows, using [¹²⁵I]-HEAT as a ligand, a 50% reduction in rat aortic alpha₁-adrenoceptors during sepsis. The maximum number of binding sites is decreased without a change in affinity (Table III), suggesting fewer ligand recognition sites. These results suggest that the decrease in number in alpha₁-adrenoceptors could contribute to the observed alterations in signal transduction.

as well as after a 1 min exposure 10 μM NE. Decreased PIP₂ labeling continues at the 1 min time points as well as at the 30 sec time point in septic aorta.

**Alphal-Adrenoceptor Alterations in Sepsis**

Since we had previously found changes in hepatic alpha₁-adrenoceptors, it was reasonable to suggest that aortic receptors might be similarly altered. Figure 3 shows, using [¹²⁵I]-HEAT as a ligand, a 50% reduction in rat aortic alpha₁-adrenoceptors during sepsis. The maximum number of binding sites is decreased without a change in affinity (Table III), suggesting fewer ligand recognition sites. These results suggest that the decrease in number in alpha₁-adrenoceptors could contribute to the observed alterations in signal transduction.

DISCUSSION

Our findings demonstrate that rat aortic alpha₁-adrenoceptor mediated PI hydrolysis, as well as alpha₁-adrenoceptors, are significantly altered in rat intraperitoneal sepsis. Studies employing rat aortic preparations in vitro have also demonstrated attenuated alpha₁-adrenoceptor responsiveness [5]; our findings suggest that at least a part of this change in responsiveness could be related to the signal transduction pathway involving alpha₁-adrenoceptors. Our findings further suggest that defects may reside in the synthesis of the substrate (i.e., PIP₂) for the nucleotide-activated phospholipase C. We have recently obtained evidence suggesting that these observed biochemical alterations have further consequences. For example, we discovered that NE-induced bidirectional calcium fluxes [37] as well as NE-induced phosphorylation of contractile proteins is similarly decreased in aortas from septic rats [30].

The mechanism of these observations is unknown and will require further investigation. The absence of changes in receptor affinity argues against the presence of a reversibly bound inhibitor. Such a substance would cause a decrease in affinity without changing the number of binding sites. Generalized receptor down-regulation as well seems unlikely since we have measured several other receptor types in this sepsis model (e.g., opiate, serotoninergic, hepatic beta adrenergic) which were unchanged (not shown).

It is significant that we were able to verify the alterations in NE-induced PI breakdown by two independent techniques. The first was the measurement of [³H]-IP accumulation in the presence of LiCl. The main advantage of this technique is its simplicity. This method has certain disadvantages which include the difficulty in measuring the predominant product (IP₃) in rat aorta. The inability to measure this metabolite in rat aorta has been seen by others [29]. We elected to use a second, independent method which entails the measurement of [³²P]-PIP₂ breakdown. Although this technique is more laborious, it gave quite similar results. These two techniques showed that the NE-induced PI hydrolysis was significantly decreased in sepsis.

It is conceivable that an endotoxin-derived molecule could elicit the biochemical changes we have discovered. Endotoxin derived molecules have been shown in vitro to activate protein kinase C [31]. It is also known that activation of protein kinase C by phorbol esters induces many of the same changes in PI metabolism in rat aorta as are found in this chronic sepsis model [32]. Thus we showed that phorbol-12,13-dibutyrate as well as phorbol-myristate diacetate attenuated the NE-stimulate PI breakdown in rat aorta [32]. It is also possible that other, unknown, factors contribute to the changes in receptor number and PI metabolism described in this paper.

It is important to note that hepatic alpha₁-adrenoceptors and vasopressin receptors are also decreased in experimental sepsis and endotoxemia models [17-20]. These findings have been demonstrated to correlate with the attenuation of alpha₁-adrenoceptor and vasopressin-receptor mediated PIP₂ breakdown, intracellular calcium release and phosphorylase activation in hepatocytes from septic and endotoxin-treated rats [20,33]. Like aorta, the liver shows a marked insensitivity to alpha₁-adrenoceptor stimulation in intraperitoneal sepsis [33-36].

In conclusion, we found that rat aortic alpha₁-adrenoceptor mediated PI hydrolysis, PIP₂ breakdown and receptor numbers were all decreased in intraperitoneal sepsis. We speculate that such alterations could contribute to the previously observed changes in aortic responsivity to NE in sepsis and endotoxemia.
