### Multilevel Security with Data Compression and Restricted Characters Set Translation

The views expressed in this thesis are those of the author and do not reflect the official policy or position of the Department of Defense or the U.S. Government.

Multilevel military communications security can be implemented with the notion of masterkeys. The naval message traffic is transmitted with restricted character set and optionally the files are compressed. Both character translation and data compression can be used as add-on data encryption. A masterkey is constructed from a set of service keys from which the masterkey is allowed to access. This thesis presents the principles of multilevel security with restricted character translation, data compression, and masterkey implementation.

ABSTRACT

Multilevel military communication security can be implemented with the notion of masterkeys. Naval message traffic is transmitted with restricted character set and optionally files are compressed. Both character translation and data compression can be used as add-on data encryption. A masterkey is constructed from a set of service keys from which masterkey is allowed to access. This thesis presents the principles of multilevel security with restricted character translation, data compression, and masterkey implementation.

I. INTRODUCTION

Multilevel security is a familiar scheme of classification in the national security hierarchy. It may partition subjects in levels of clearance and divide objects into levels of classification [Ref. 1]. This thesis reports one implementation that supports multilevel security with a Master Key [Ref. 2] and is suitable for naval message traffic by data compression and character translation. Data compression reduces original data package size for better storage and transmission capacity, while character translation converts each byte of an input file to a restricted character set since naval message traffic uses a restricted character set.

A shore-based system includes a large database which consists of relational tables of ASCII data in a commercial RDBMS (Relational Database Management System) as well as associated ASCII text and binary (graphic) files. Packages of data are prepared from the database for subsequent delivery to remote systems via floppy disks, an electronic network, or via standard naval message traffic. Each prepared data package consists of a combination of ASCII and binary files grouped together in the standard hierarchical file storage structure of the host system. After either physical or electronic delivery of a data package, it resides within the file storage of the remote system.

The processes of data compression is followed by data encryption prior to passing the processed file on to the character translation process. The entire scenario is then
Figure 1. The scenario of data package transmission on Naval message traffic.

repeated in the reverse direction at the remote site as shown in Figure 1. A data compression algorithm is investigated based on its conflicting efficiencies of CPU time and compression ratio. When urgency does not dictate action, the compression ratio is more important than execution time. Data encryption is an optional requirement that allows different encryption schemes to be chosen. Without a hardware encryption chip available to us, DES (Data Encryption Standard) [Ref. 3] has been implemented by software that incorporates the Master Key routines. As an unclassified research, this thesis uses the UNIX crypt() routine for illustration.

Though designed for different purpose, all three methods used in this research
contribute to data security: data compression, data encryption, and character translation. When all methods are employed, the overall data security is greatly enhanced since the probability of decoding by adversaries is the product of probabilities in breaking each process individually.

In Chapter II, data compression techniques are briefly overviewed. Chapter III discusses the incorporation of Master Keys for supporting multilevel security systems and data encryption. Chapter IV introduces the algorithm for character translation. The concluding remarks are given in Chapter V.
II. A CASCADING DATA COMPRESSION TECHNIQUE

Regardless of the compression algorithm used [Ref. 4, 5, 6, 7, 8], a compressed file can actually provide the first level of encryption since the compressed file consists of random bit patterns and mostly non-printable characters. Because all compression algorithms do not have byte-for-byte correspondence between the source file and the compressed file, each byte of the compressed file can not be reversed back to original bit pattern unless the compression algorithm is known.

The data compression software we use for implementing multilevel security access control and restricted character translation is the "ZIP" program written by Richard B. Wales et.al [Ref. 9]. The program includes three compression routines that may be chosen by the user. Each routine implements a different compression technique. In this chapter we overview the "Implode" routine. Implode is the best of the three algorithms and is known to be one of the fastest and most powerful schemes for data compression in terms of execution speed and compression ratio. The compression algorithm of "Implode" is actually a combination of two distinct algorithms. The first algorithm is OPM/L (Original Pointer Macro restricted to Left pointers) compression scheme which compresses repeated byte sequences using a sliding dictionary (window). The second algorithm is Shannon-Fano coding which uses multiple variable-length binary encoding of various parts of the OPM/L output.
A. THE OPM/L COMPRESSION ALGORITHM DEVELOPMENT

An OPM/L data compression scheme called LZ77 was first suggested by Ziv and Lempel [Ref. 6]. A slightly modified version of this scheme which improves the compression ratios for a wide range of texts, developed by Storer and Szymanski, is called LZSS [Ref. 10] and has fast decoding and requires comparatively little memory for coding and decoding.

An OPM/L scheme replaces a substring in a text with a pointer to a previous (left) occurrence of the substring in the text. The pointer represents the position and size of the sub-string in the original text. These restrictions make fast single-pass decoding straightforward. The LZ77 scheme restricts the reach of the pointer to approximately the previous N characters, effectively creating a "window" of N characters which are used as a sliding dictionary. Pointers are chosen using a greedy (seeking for longest match) algorithm which permits single-pass encoding. Therefore a LZ77 encoder is parameterized by N, the size of the "window", and F, the maximum length of a substring that may be replaced by a pointer. Encoding of the input string proceeds from left to right. At each step of the encoding a section of the input text is available in a window of N characters. Of these, the first N - F characters have already been encoded and the last F characters are the "lookahead buffer". For example, if the string $S = \text{abcabcbababcabcabc} \ldots$ is being encoded with the parameters $N = 11$, $F = 4$ and character 12 is to be encoded next, the window is as shown in Figure 2.

Initially the first N - F characters of the window are (arbitrarily) blanks, and the first F characters of the text are loaded into the lookahead buffer. The already encoded
part of the window is searched to find the longest match for the lookahead buffer, but obviously it can not be the lookahead buffer itself. In the example, the longest match for the "babc" is "bab", which starts at character 10. The longest match is then encoded into a triple <i, j, a>, where i is the offset of the longest match from the lookahead buffer, j is the length of the match, and a is the first character which did not match the substring in the window. In this example, the output triple would be <2, 3, 'c'>. The window is then shifted right j + 1 characters, ready for another coding step. Decoding is very simple and fast. The decoder maintains a window in the same way as the encoder, but instead of searching for a match in the window it uses the triple given by the encoder.

The main disadvantage of LZ77 is that, a straightforward implementation can require up to (N - F)•F characters comparisons, typically on the order of several thousands. The performance of different compression schemes with the parameters of speed and memory is listed in Table I.

An improved technique for reducing the time for compression was introduced by T.C.Bell [Ref. 4] since time is the only point when LZ77 or LZSS techniques fall short of other algorithms that are shown in Table I. The algorithm developed by Bell is the

"Binary Tree Algorithm" that searches for the longest match for a string. Consider the same string $S$ at page 5 with the same parameters $N = 11$ and $F = 4$, and coding is up to character 12 as shown in Figure 3.

```
5  6  7  8  9  10  0  1  2  3  4
 b c b a c b a b a b c

| lookahead buffer |
```

Figure 3. Encoding window of Binary Tree Algorithm.

The lookahead buffer is defined as $L = x_1 = babc$ and $x_2 = bcba$, $x_3 = cbac$, $x_7 = bacb$, $x_8 = acba$, $x_9 = cbab$, $x_{10} = baba$, $x_0 = abab$. By inspection, the longest match
is $x_{10}$ with vector $(1, x) = (10, 3)$ where 10 is the position of the match string start and 3 is the characters that match the lookahead buffer.

The binary search algorithm starts with sorting the $x_5, x_6, ..., x_0$ with Literal order. So we have:

$x_0 \ x_8 \ x_{10} \ L \ x_7 \ x_5 \ x_9 \ x_6$

abab acba baba babc bacb bcba cbab cbac

The longest match for $L$ should be found at the beginning of $x_{10}$ or $x_7$. This happened because these two strings are Literal adjacent to the lookahead buffer $L$ and are the two candidates for the longest match.

The basic construction of the tree is that for any node $x_i$ all nodes in its left subtree are Literal less than $x_i$ and all nodes in its right subtree are Literal greater than $x_i$. Therefore the tree is constructed starting with $x_5, x_6, x_7, ..., x_{10}, x_0$, $L$ and then $x_{10}$ and $x_7$ appear on the path to $L$ as shown in Figure 4, where the algorithm for encoding and binary tree searching will be discussed in Section II. C.

B. SHANNON-FANO CODING ALGORITHM

The Shannon-Fano technique [Ref. 15] has as an advantage its simplicity. The code is constructed as follows. The source messages $a_i$ and their probabilities $p(a_i)$ are listed in order of nonincreasing probability. This list is then divided in such a way as to form two groups of as nearly equal total probabilities as possible. Each message in the first group receives 0 as the first digit of its codeword; the messages in the second half have
codewords beginning with 1. Each of these groups is then divided according to the same
criterion, and additional code digits are appended. The process is continued until each
subset contains only one message.

Figure 5 shows the application of Shannon-Fano algorithm to a specific probability
distribution. The length of each codeword is equal to \(-\log_2 p(a)\). This is true as long as
it is possible to divide the list into subgroups of exactly equal probability. When this is
not possible, some codewords may be of length \(-\log_2 p(a_i) + 1\). The Shannon-Fano
algorithm yields an average codeword length \(S\) that satisfies \(H \leq S \leq H + 1\), where \(H\)
is the entropy of the source. The Shannon-Fano code for the ensemble "aa bbb cccc
dddddd eeeeee ffffffff gggggggg" is shown in Figure 6.

**C. SOFTWARE IMPLEMENTATION**

The cascading of OPM/L and Shannon-Fano scheme in the Imploding algorithm can use a 4K \( (N = 4096) \) or 8K \( (N = 8192) \) sliding dictionary size. The dictionary size used
can be determined by bit 1 in the general purpose flag word of "Local file header" [Ref. 11].

The Shannon-Fano trees are stored at the beginning of the compressed package. The number of trees stored is defined by bit 2 in the general purpose flag word. If 3 trees were stored, the first tree represents the encoding of the literal characters, the second tree represents the encoding of the Length information, the third represents the encoding of the distance information. When 2 Shannon-Fano trees are stored, the Length tree is stored first, followed by the distance tree.

The Literal Shannon-Fano tree, if presented, is used to represent the entire ASCII character set, and contains 256 values. This tree is used to compress any data not compressed by the sliding dictionary algorithm. When this tree is presented, the Minimum Match Length (MML) for the sliding dictionary is 3. If this tree is not presented, the MML is 2. The Length Shannon-Fano tree is used to compress the Length part of the (length, distance) pairs from the sliding dictionary output. The Length tree contains 64 values, ranging from the MML to MML + 63. The distance Shannon-Fano tree is used to compress the Distance part of the (length, distance) pairs from the sliding dictionary output. The Distance tree contains 64 values, ranging from 0 to 63, representing the upper 6 bits of the distance value. The distance values themselves will be between 0 and the sliding dictionary size, either 4K or 8K.

The Shannon-Fano trees themselves are stored in a compressed format. It can be constructed from the bit lengths using the following algorithm:
1) Sort the Bit Lengths in ascending order, while retaining the order of the original lengths stored in the file.

2) Generate the Shannon-Fano trees using the routine in Figure 7.

```plaintext
Code <- 0
CodeIncrement <- 0
LastBitLength <- 0
i <- number of Shannon-Fano codes - 1 (either 255 or 63)

loop while i ≥ 0
   Code = Code + CodeIncrement
   if BitLength(i) <> LastBitLength then
      LastBitLength = BitLength(i)
      CodeIncrement = 1 Shifted left (16-LastBitLength)
   ShannonCode(i) = Code
   i <- i - 1
end loop
```

Figure 7. Algorithm for generating Shannon-Fano trees.

3) Reverse the order of all the bits in the ShannonCode() vector, so that the most significant bit becomes the least significant bit. For example, the value 0x1234 (hex) would become 0x2C48 (hex).

4) Restore the order of Shannon-Fano codes as originally stored within the file.

Let's give an example which will show the encoding of a Shannon-Fano tree of size of 8. Notice that the actual Shannon-Fano trees used for Imploding are either 64 or 256 entries in size.

For example given: 0x02, 0x42, 0x01, 0x13.

The first byte indicates 3 values in this table. Decoding the bytes:
0x42 = 5 codes of 3 bits long
0x01 = 1 code of 2 bits long
0x13 = 2 codes of 4 bits long

This would generate the original bit length array of:

(3, 3, 3, 3, 3, 2, 4, 4)

There are 8 codes in this table for the values 0 through 7. Using the algorithm to obtain the Shannon-Fano codes step by step will produce the result as in Figure 8.

**Figure 8.** Decoding steps of Shannon-Fano scheme.

The values in the 'Val', 'Order Restored' and 'Original Length' columns now represent the Shannon-Fano encoding tree that can be used for decoding the Shannon-Fano encoded data. The compressed data stream begins immediately after the compressed Shannon-Fano data. The compressed data stream can be interpreted by the algorithm shown in Figure 9.

Since pass two (Shannon-Fano tree) depends on a statistical analysis of the entire
loop until done
    read 1 bit from input stream.

    if this bit is non-zero then (encoded data is literal data)
        if Literal Shannon-Fano tree is present
            read and decode character using Literal Shannon-Fano tree.
        otherwise
            read 8 bits from input stream.
            copy character to the output stream.
    otherwise (encoded data is sliding dictionary match)
        if 8K dictionary size
            read 7 bits for offset Distance (lower 7 bits of offset).
        otherwise
            read 6 bits for offset Distance (lower 6 bits of offset).

using the Distance Shannon-Fano tree, read and decode the upper 6 bits of the Distance value.

using the Length Shannon-Fano tree, read and decode the Length value.

Length <- Length + Minimum Match Length

if Length = 63 + Minimum Match Length
    read 8 bits from the input stream,
    add this value to Length.

move backwards Distance+1 bytes in the output stream, and copy Length characters from this position to the output stream. (if this position is before the start of the output stream, then assume that all the data before the start of the output stream is filled with zeros).

end loop

Figure 9. The OPM/L decoding algorithm.

output of pass one (OPM/L compression), the output of pass one is saved in a temporary file and re-read for pass two. Imploding is thus a two-pass algorithm.

data type files in compression ratio (% of original file size). Clearly, the cascading of OPM/L and Shannon-Fano scheme has a far better performance than others. The EXE file exhibits a higher ratio because of the poor compression performance for binary files [Ref. 12]. Run-length encoding may take advantage of long string of binary images which is not the main subject of this research. A complete comparison of data compression efficiency in terms of compression ratio and execution time can be found in Jung [Ref. 12].
III. DATA ENCRYPTION WITH MASTER KEY IMPLEMENTATION

When a data package is transmitted to remote systems, compressed or not, if encryption is requested by user, the access control of the encrypted package is then of principal concern. When several parties require shared access to a secure data package, it is convenient to partition the packages into several classes (multilevel) and encrypt each class individually. A key management problem can be avoided by providing a Master Key to permit access to the required classes. In this chapter, the Master Key scheme is introduced and implemented to support multilevel security.

A. THE MASTER KEY SCHEME

1. Master Key Systems

The brief overview of Master Keys in this section is based on [Ref. 2] which is an improvement to [Ref. 13]. A Master Key is a compact representation for a subset of the service keys. In the following discussion, the ‘≤’ indicates a partial order subordinating relation. Each $S_i$ is assigned a service key $SK_i$. If $S_i \leq S_j$, then service (an object) $S_i$ is subordinated to $S_j$ and access to $S_j$ guarantees access to $S_i$.

Each service is assigned a small prime $p$, but no primes are assigned to the Central Authority (CA) or Master Keys user. Let

$$T = \prod_{n=1}^{N} p_n.$$
For each service a number $u_i$ is defined as

$$u_i = \prod_{x \leq x_j} P_n,$$

and the service key is defined as

$$SK_j = K_0^{u_i}.$$

$K_0$ is a random key number chosen by the central authority. The Master Keys can be made by the following mechanism. First, $v_j$ is computed as

$$v_j = \prod_{x \leq x_j} P_n,$$

where the set

$$\{ SK_j \leq MK_j \}$$

consists of all the keys for services accessible with Master Key $MK_j$. The Master Key is defined as

$$MK_j = K_0^{v_j}.$$

The computation of a service key from a Master Key is then
Note that in this chapter, the arithmetic is performed in \((\mod M)\) for some integer \(M\). Values are operated in the ring of integers \((0, M - 1)\) where \(M\) is defined by

\[
M = p_1 \cdot p_2
\]

for some large primes \(p_1\) and \(p_2\) similar to the RSA algorithm [Ref. 14].

2. Flexibility of Master Key algorithm

Computation of a service key is feasible if and only if \(SK_i \leq MK_j\). If \(SK_i \leq MK_j\), then (by definition) all primes in \(u_i\) must be included in \(v_j\), thus, \(u_i\) divides \(v_j\). \((MK_j)^{v_i/u_i}\) is easily computed as in equation (1) since \(v_j/u_i\) results in an integer.

a. Prohibition of non-MasterKey intrusion

When \(SK_i \neq MK_j\), the access is denied as follows. Let

\[
u_j = \alpha \cdot p_i, \quad MK_j^{v_i/u_i} = \left[ (MK_j^{p_i})^{v_i} \right]^{1/\alpha}.
\]

Where \(p_i\) does not divide \(v_j\), and the \(p_i^{th}\) root of \(MK_j\) must be computed. But computing the \(r^{th}\) roots mod \(M\) for \(r > 1\) is believed to be as difficult as factoring \(M\) [Ref. 3]. So when \(p_i\) does not divide \(v_j\), \(MK_j^{v_i/p_i}\) cannot be computed if the factors of the modulus are unknown. This prohibits the unauthorized access when \(M\) is large.
b. Prohibition of grouped intrusion

The Master Key is also secure against illicit cooperation where a group of people may have sufficient information to do things none of them are capable of individually. A sufficient condition is that no group of Master Keys can be used to gain access to additional services. That is, from a group of Master Keys we cannot create a key MK, such that SK, \( \leq MK \), if none of the keys in the group have access to service \( S_j \). This has been proven in [Ref. 2] since \( p_i \) is not a factor of \( v_j \) in any Master Key of the group.

c. Expansion capability

[Ref. 2] also proved that it is possible to add services to the system, without affecting existing keys, provided that a new addition is not subordinate to any existing service. Hence a new service added will introduce the equation to compute \( SK \), as

\[
SK_{N+1} = (K_0')^{T'} \left( u_{N+1} \right)^{T'}
\]

Where

\[
K_0' = (K_0)^{P_{N+1}} \cdot
\]

\[
T' = T \cdot P_{N+1} \cdot
\]

\[
u_{N+1} = \prod_{S_n \subseteq S_{N+1}} P_n \cdot
\]
and \( SK_{N+1} \) is the new service added.

Although the keys are unchanged by the substitution of \( T' \) and \( K_{u'} \), but this manner bring up the new problem that number of services to be added is constrained by the relatively primes to \( M \), for instance, if \( M = p_1 \times p_2 \), then the maximum number of service key that can be expanded is 2. In addition, since the new prime \( p_{N+1} \) is not a factor of \( v_j \) for any of the existing keys, new Master Keys have to be redistributed by the CA to accommodate the \( \leq \) relationships.

We notice that \( T \) value (products of all primes) is the burden which makes system expansion inflexible. \( T \) must be fixed or all key numbers have to change accordingly since \( T/u_i \), or \( T/v_j \) provides the power of \( SK_i, MK_j \). In our experiment, we introduce another method for Master Key system expansion. Numbers of individual services are assigned in the beginning when a system was built according to future expansion consideration. These services originally can be either \( \leq \) or doesn’t \( \leq \) to any service or Master Key, but primes are assigned to them as usual service key. Thus, \( T \) value will not be affected when any of these services is assigned to be a new service key, and the new service key can be inserted (or activated) in between two existed service keys or under any Master Key as required, the only value has to be modified is the \( u_i \) or/and related \( v_j \) when insertion takes place.

**B. EXAMPLE OF A MULTILEVEL SECURITY MODEL**

To implement the concept of Master key scheme on compressed/encrypted data package, we constructed a multilevel hierarchy of 70 services as illustrated in Figure 10.
Each service can be treated as an encrypted data package. To access (decrypt) an encrypted package $S_i$ from $S_j$ or by $MK_j$, the subordinating relationship either $S_i \leq S_j$ or $S_i \leq MK_j$ must be satisfied respectively.

In Figure 10 the $\leq$ relationships among services are shown by covering over the inferior one in vertical order. For example, the leftmost column shows that $S_{08} < S_{09}$, $S_{07} < S_{08}$ etc. Therefore, a Master Key that can access a service $S_i$ can also access all the services inferior to $S_i$. Thus, if a Master key $MK \geq SK_i$, then this MK can access $SK_{i-1}$, $SK_{i-2}$, ... as well, provided that $SK_{i-1}$, $SK_{i-2}$, ... are connected and been covered. Consequently, this Master key is called $MK_i$.

Additionally, there are eight other Master keys ($MK_j$, $j = 0, 1, ..., 7$) shown as shaded arrows in Figure 10. Each $MK_j$ covers or is superior to services connected by a line. For example, $MK_0$, has a line going through $S_{09}$, $S_{18}$, $S_{27}$, $S_{36}$, $S_{45}$, $S_{54}$, $S_{63}$ and therefore $SK_{09} \leq MK_0$, $SK_{18} \leq MK_0$, ..., $SK_{63} \leq MK_0$. Table A in Appendix B lists the corresponding prime number assignments for Figure 10. For instance, the prime number for $S_{10}$ is 349.

1. Example of access control

As an instructive example, let's arbitrarily pick $S_{35}$ as an encrypted data package to access. Figure 10 shows $SK_{35} \leq MK_0$ ($SK_{35} \leq SK_{36} \leq MK_0$), $SK_{35} \leq MK_3$, $S_{35} \leq S_{36}$, etc. Hence, there are 8 Master Keys that can access $S_{35}$:

$$\{ MK_0, MK_3, MK_5, MK_{35}, MK_{36}, MK_{37}, MK_{38}, MK_{33} \}$$ (4)
The number $u_{35}$ is computed as

$$u_{35} = \prod_{j=30}^{38} p_i = 229 \cdot 227 \cdot 223 \cdot 211 \cdot 199 \cdot 197 \quad (5)$$

Two parameters are needed for key number computation: First, $M = 2147483641L$ is arbitrarily chosen such that $M$ is close to $2^{31}$ and $M >> (p_0 \cdot p_1)$. This $M$ can be supported by a 32-bit unsigned "long" integer in C. Next, a randomly picked $K_0 = 1992$ is used. Now the service key for $S_{35}$ is
\[ SK_{35} = \mod\left( K_0 \prod_{m=1}^{i} P_{m-i} \right) \quad \text{for } i = 30, 31, 32, 33, 34, 35. \quad (6) \]
\[ = 1989952527L \]

Table B in Appendix B lists all the service keys. We now show how the Master Key \( MK_3 \) can access \( S_{35} \) by making \( SK_{35} \) from \( MK_3 \). The value of \( v_3 \) has to be computed first.

\[ v_3 = \left( \prod_{j=30}^{39} P_j \right) \cdot P_{20} = 179 \cdot 181 \cdot \ldots \cdot 229 \cdot 281 \quad (7) \]

Therefore,

\[ MK_3 = 1992 \prod_{n=3}^{\infty} P_n \quad \text{for } n \neq j, j = 30, 31, \ldots, 39, 20. \quad (8) \]
\[ = 0002255128L \]

With \( MK_3 \) one can derive \( SK_{35} \):

\[ MK_3^{\frac{v_3}{405}} = \mod\left( \frac{P_{28} \cdot P_{27} \cdot P_{26} \cdot \ldots \cdot P_{35}}{P_{30} \cdot P_{31} \cdot \ldots \cdot P_{35}} \right) \]
\[ = \mod\left( (2255128)^{P_{28} \cdot P_{27} \cdot P_{26} \cdot P_{25}} \right) \]
\[ = \mod\left( (2255128)^{281 \cdot 193 \cdot 191 \cdot 181 \cdot 179} \right) \]
\[ = 1989952527L = SK_{35} \]
In other words, $MK_3$ can access service $S_{35}$.

2. Example of intrusive prevention

On the other hand, let's see whether $MK_7$ (it is not in set (4)) can access $S_{35}$. Since

$$V_7 = P_{40} \cdot P_{41} \cdot P_{50} \cdot P_{51}$$

$$= 173 \cdot 167 \cdot 113 \cdot 109 = 355850447L$$

and

$$MK_7 = \mod(1992^{n}) \quad \text{for } n \neq j, j = 40, 41, 50, 51.$$

$$= 1479772666L$$

To make the service key $SK_{35}$ from $MK_7$, one may try the following.

$$\frac{V_7}{MK_7 \cdot u_{35}^{P_3}} \equiv (1479772666) \cdot (P_{40} \cdot P_{41} \cdot P_{50} \cdot P_{51}) \mod(1992^{n})$$

Let

$$a = P_{30} \cdot P_{31} \cdot P_{32} \cdot P_{33} \cdot P_{34}.$$

Equation (11) becomes
Since $p_{35}$ does not divide into $\nu_7$, $MK_7$ can not access $S_{35}$ and computing the $p_{35}$\textsuperscript{th} root to factor $p_{35}$ out will be difficult; never even mention the modulus number 2147483641L. With same computation model, one can show that all Master Keys in set (4) can access $S_{35}$, but none of the others can. It is also shown that a Master Keys constructed from a group of Master Keys which are not in set (4) access $S_{35}$ either, since $p_{35}$ (197) does not divide any $\nu$ of them. This prevents the grouped intrusion.

C. SOFTWARE IMPLEMENTATION

Recall the scenario of the Naval message traffic described in Chapter I. If data encryption is required, it has to be done after data compression and before the characters set translation at the host system. In the software implementation (see Appendix A), user may provide the password (key) for encryption after data compression (at host system) or data recovery (at remote system). Given a correct key the program will encrypt or decrypt the file; otherwise the program assumes no data encryption.

Command line options allows a user to modify an encrypted file without explicitly decrypting it. But when using this option a user still has to provide the decryption key, The whole procedure is as follows:

[recovery] $\rightarrow$ decryption $\rightarrow$ modification $\rightarrow$ encryption $\rightarrow$ [translation].

In this case, the password for encryption procedure is automatically derived from
file header of the decryption process. In the next two sections, we will discuss how passwords are verified in the Master Key access control environment and how data encryption is implemented. The C program listing can be found in Appendix A.

1. Master Key access control

Access control is divided into two steps: password conversion and key number computation.

```
  first 2 numbers = first byte (of password) convert to ASCII;
  third number = second byte - 49 (ASCII);
  fourth number = third byte - 52 (ASCII);
  fifth number = fourth byte - 55 (ASCII);
  sixth and seventh number = fifth and sixth byte;
  eighth number = seventh byte - 58 (ASCII);
  ninth number = eighth byte - 61 (ASCII);
  tenth number = ninth byte - 64 (ASCII);
  key number = conversion all ASCII number to type long;
  identify number (u, or v) = last 2 bytes of password;
  return key number;
```

Figure 11. Password conversion algorithm.

a. Key to Password Conversion

As specified in section III. B. To facilitate the friendly use by the users, passwords are used instead of the keys, The key to password conversion can be done in several ways. Here we present one way that is easily implemented. A key number is implemented as a 10-digit number since the chosen modulo number is 2147483641. Key number as well as the index number of v (u) are converted to a 11-character password by simply performing the shift and translation as shown in Figure 11. Hence, SKv,
(0015206469L) is converted to 'abii06nsy2O'. In Appendix B, Table B, all Master Key numbers and passwords are listed.

At the host system, the user password is examined to avoid the data package being ruined by an invalid password. Verified password is then itself encrypted and embedded in the file header starting at the 4th byte. At the remote system, the received file header will be examined to see if it was a encrypted file. If it is encrypted, the 11 bytes starting at 4th byte in header will be used for service key number conversion. Meanwhile, the user must provide the password for key computation. In Appendix B, all Master Key numbers and passwords are listed.

b. Service key number computation

In using the Master Key, it is assumed that there is no password distributed electronically and the access is done by key number computation. The Master Key numbers are not necessary to be the same as service key numbers before computation. Therefore, different Master Key numbers may result same service key number based on a unique  $v_j$.

Recall the discussions in sections A, and B, the modulus operation was taken in each arithmetic operation. While implementing in software, care has to be taken that modulus operation will not work if it is trying to mod a key number result as in (1), since multiple more prime numbers normally produce a large digits number. Without memory concatenation, the product result will be truncated and become useless before modulus process because the Floating Point Number System allows limited digits (Mantissa) representation, (e.g. IEEE-double precision has 53 bits [Ref. 16]). An
example here is the $T$ value by definition:

\[
T = \prod_{n=0}^{69} P_n = 409 \cdot 401 \cdot 397 \cdot \ldots \cdot 37 \cdot 31 \tag{12}
\]

It results a number that has more than 70 digits and cannot be easily represented. Moreover, since the products of primes will become the power of $K_0$, no Floating Point Number System can support such large value. To solve this problem, a procedure we called "wrapping" is implemented in software as listed in Appendix A. Modulus operation is now beginning at first $k_0$, and repeat in each multiplication until the end, to restrict each result in the range $[0, 2147483640]$. Now (1) becomes

\[
SK_i = \frac{T}{\prod_{n=0}^{69} P_n} = \frac{\prod_{n=0}^{69} P_n}{\prod_{n=0}^{69} P_0} = \mod(k_0^{\frac{T}{\prod_{n=0}^{69} P_n}}) = \mod(k_0^{\prod_{n=0}^{69} P_n}) = \mod(k_0^{P_a P_b \cdots P_n}) \quad \text{for } S_a, S_b, \ldots, S_n \notin S_i
\]

\[
= \mod(\mod(\ldots \mod(\mod(k_0^{P_a})^{P_b}) \ldots)^{P_n})
\]
Furthermore, to prevent a large prime number as a power, any inner term in (13) can be divided into

\[ \mod\left( m^p \right) = \mod\left( \ldots \mod\left( \mod\left( m \right) \cdot m \right) \ldots m \right)_p \quad (14) \]

Key number computation is implemented only at the remote system right after password conversion. If the Master Key number after computation is equal to the service key number, picked up from file header, then the program will decrypt with the password obtained from the file header. The algorithm for password verification and key number computation is shown in Figure 12.

2. Data encryption

Encryption on a compressed data package is an option to user. It may be specified at the command line when executing the software at the host system. If it is requested, the function encrypt() will process after password is verified. At remote system, program will automatically get the first 3 bytes in file header to check if it is an encrypted file and verify the key. Notice that encryption algorithms are varied from user to user, so are the password encryption of file header and key number conversion. They can be implemented in different schemes to meet the data security requirements, for example the DES. After all, the Master Key scheme will not be affected by different encryption schemes and it drives the access control.

In this experimentation we used the UNIX crypt() (the key generation part from "Makekey" has been modified to Master Key password conversion) routine for
loop: request user enter password;
    if user password == header password: (the case of encrypted user)
        proceeding decryption;
    else if length of password != 11:
        if over three tries:
            recover original file and exit;
        else
            display error message then go to loop;
    else
        passw2num(user password);

encrypted key number = passw2num(header password);
initial for key computation;
if Master Key user:
    get belonging service list matrix;
    loop to product of relate primes (v) times:
        keynum_mod();
else (the case of superior service keys)
    loop to product of relate primes (u) times:
        keynum_mod();

if computed key number == encrypted key number:
    proceeding decryption;
else
    if over three tries:
        recover original file and exit;
    else
        display error message then go to loop;

Figure 12. Password verification algorithm.

from "Makekey" has been modified to Master Key password conversion) routine for illustration. It is a one-rotor machine encryption algorithm designed along the lines of Enigma but considerably trivialized, encryption and decryption uses the same key. Each
included 3 bytes for encryption distinguish and 11 bytes for password (it is the keyword to encrypt too). Encrypted data packages must be decrypted before they can be decompressed. To decrypt a package, a shift operation is used to decrypt the 11-byte keyword for the encryption key which in turn decrypts the compressed data stream if the password has been verified.
IV. RESTRICT CHARACTER SET TRANSLATION

Since Naval message traffic uses the restricted character set listed in ntp3 annex C, the compressed and/or encrypted package has to be translated using this restricted character set. A restricted character set of $N$ symbols can be represented as

\[ C = \{ a_1, a_2, \ldots, a_N \} \quad \text{where} \quad N \leq 256. \] (15)

Without loss of generality, it is assumed that the restricted 45 ($N$) characters are in the contiguous decimal value interval [46, 90] (ASCII '.' to 'Z'). In a source package (without character translation) each input byte of 8 bits can assume $2^8 = 256$ various bit patterns and all patterns are equally likely to occur. When mapping a byte of 8-bit to one of the 45 restricted character, one may let 40 bit patterns uniquely map to corresponding 40 characters; the mapping of other 216 patterns have to use 2 characters each. On the average, the translated file is expanded to 185% of the original file since

\[ \frac{40}{256} \times 1 + \frac{216}{256} \times 2 = 1.84375 = 184.37\% \text{.} \]

The expansion ratio (85%) is unacceptably high therefore a source file must be translated in blocks of bits ($< 8$) when data compression efficiency is concerned. Since $N = 45$, $5 < \log_2(45) < 6$. Thus, the bit pattern to be translated could be blocks of either 5-bit or 6-bit depending on the efficiency of expansion ratio to be discussed below.
A translated character (8 bits) can represent a block of either 5-bit or 6-bit of input bit stream. This implies that an output byte (character) always starts with a '0' bit and the other 7 bits vary in 45 patterns. Hence, a shift operation is needed to output a byte in the desired range. Three basic translation methods are discussed as follows:

1). Scan input stream in 6-bit blocks. Since a 6-bit block may form 64 different patterns, with only 45 characters to map there are 44 lucky 6-bit pattern that can map to a single character in expression (15) whereas the rest of 20 patterns have to be translated in two combined characters \( \alpha_4 \alpha_5, i \neq 45 \).

2). Scan input stream in 5-bit blocks. Since a 5-bit block may span 32 different patterns, with 45 characters to map there are 13 characters in the restricted character set unused.

3). This is an improvement to the second method. 13 unused characters are assigned to corresponding 6-bit patterns. It scans input stream in 6-bit blocks, examines the values and will translate 6-bit block whenever possible.

A. EXPANSION RATIOS

It can be shown that the first two methods are not as efficient as the third method. Without a prior knowledge of the source stream, it is reasonable to assume that all bit patterns are equally likely in the following discussions. Let \( b_1, b_2 \) be the number of bits used to encode a translated character (byte) and \( p_{b1}, p_{b2} \) be the corresponding probabilities of occurrences in translation. The expansion ratio \( \eta \) of method 1 is then
\[ \eta = \frac{(8 - b_1)}{b_1} (p_{b1}) + \frac{(8 \times 2 - b_2)}{b_2} (1 - p_{b2}) = 0.75 - 75\% \quad (16) \]

where

\[ b_1 = 6, \quad p_{b1} = \frac{44}{64} = 0.688 \]

\[ b_2 = 6, \quad p_{b2} = 1 - p_{b1} = 0.312 \]

In equation (16), the second term indicates that we expand from 6 bits to 2 bytes for the 20 unlucky 6-bit patterns. Similarly, we can compute the expansion ratio for the second method as

\[ \eta = \frac{8 - 5}{5} = 0.6 \rightarrow 60\%. \]

For the method 3, \( b_1 = 6, b_2 = 5 \), thus

\[ \eta = \frac{(8 - 6)}{6} \left( \frac{13}{64} \right) + \frac{(8 - 5)}{5} \left( \frac{51}{64} \right) = 0.546 \rightarrow 54.6\%. \quad (17) \]

The third method provides the best of all three translation methods and is very close to set standard of 50\%.

Variants of the method 3 can increase the probability of 6-bit block pattern translation. But, they are not as efficient as the method 3. For example, when \( N = 45 \),
one may assign 16 patterns for 4-bit and 29 patterns for 6-bit. Two other variants are (1) 8 patterns for 3-bit and 37 patterns for 6-bit and (2) 4 patterns for 2-bit and 41 patterns for 6-bit. We calculate the corresponding expansion ratio for each case as follows:

- 29 patterns for 6-bit with others for 4-bit :

\[
\eta = \left(\frac{8 - 6}{6}\right) \left(\frac{29}{64}\right) + \left(\frac{8 - 4}{4}\right) \left(\frac{35}{64}\right) = 0.698 \rightarrow 69.8\%
\]

- 37 patterns for 6-bit with others for 3-bit :

\[
\eta = \left(\frac{8 - 6}{6}\right) \left(\frac{37}{64}\right) + \left(\frac{8 - 3}{3}\right) \left(\frac{27}{64}\right) = 0.896 \rightarrow 89.6\%
\]

- 41 patterns for 6-bit with others for 2-bit :

\[
\eta = \left(\frac{8 - 6}{6}\right) \left(\frac{41}{64}\right) + \left(\frac{8 - 2}{2}\right) \left(\frac{23}{64}\right) = 1.292 \rightarrow 129.2\%
\]

All the results are worse than the method 3 because the second term in each calculation grows faster than the reduction of the corresponding probabilities. Moreover, it is impossible to translate more than 6 bits in each decision when \(N < 64\). To generalize the \(\eta\) computation of method 3 for restricted character set of size \(N\) in the range \([2, 256]\) the \(\eta\) can be calculated as follows:
\[
\eta = \frac{(8-b_1)}{b_1} (p_{b_1}) + \frac{(8-b_2)}{b_2} (p_{b_2})
\]

(18)

\[
b_1 = \lceil \log_2 (N) \rceil, \quad p_{b_1} = \frac{N - 2^{\lfloor \log_2 (N) \rfloor}}{2^{\lfloor \log_2 (N) \rfloor}}
\]

\[
b_2 = \lfloor \log_2 (N) \rfloor, \quad p_{b_2} = 1 - p_{b_1}
\]

COMP : Compressed only. 
\( \eta \) : Expansion ratio due to translation. 
C&R : Compressed and Translated. 
%ORG : % of original file size.

The equation (18) is similar to equation (17) except that it is now parameterized with \( N \). Theoretically, by taking the expansion ratio 54.6% of equation (17) with an average compression ratio around 39.3% (derived from Table II, 'PAK' file), the compressed and translated file size would be about 39.3% \times (1 + 54.6\%) \approx 60.77\%.
of original file size. Table III shows testing results of different type of files after compression and character set translation. The expansion ratios in 4th column agrees with the theoretical value in equation (17). The larger variance among testing results, however, is shown in the last column ("C&R %ORG" column) when both compression and translation are performed. This is due to the different file type benefits different compression ratio. It is interesting to note that PAK file (combination of 90% ASCII text and 10% image binary data which is a Data Representation Format specified by the Navy) size shown in 5th column becomes "C&R" 60.4% of original file, fairly close to theoretical ratio (60.77%) described above.

![Figure 13. Expansion ratio with variable character numbers.](image)

Figure 13 shows the plot of equation (18). The expansion ratio decline sharply before N reaches 16. Notice the stairlike steps when N is a power of 2, ratio curve doesn't continuously vary with N. This because the ratios analysis based on theoretically computes the translated bits corresponding probabilities. In software implementation, the
bit-shift manipulation may improve the expansion ratio as will be explained in Section 3.

B. SOFTWARE IMPLEMENTATION CONSIDERATION

A C program (See Appendix A) based on method 3 was implemented. We now describe the algorithm that has been incorporated in a compressed/encrypted data package. The character set translation algorithm has two separate parts: translation (at host system) and recovery (at remote system).

1. Translation Algorithm

The translation algorithm scans the input stream, however, in 6-bit blocks before committing to a translation. We may assign 32 restricted characters ('.' through 'M') to decimal values interval [0, 31] for 5-bit blocks and the other 13 characters ('N' through 'Z') to the interval [32, 44] for 6-bit blocks. If the value of the 6-bit block is in the interval [32, 44], then the block is translated to the corresponding character. When the value is not in the range of [32, 44] then it is either in [0, 31] or in [45, 63]. The algorithm shifts one bit backward (unget) making the value reside in interval [0, 31] and translates the 5-bit block. In the following discussion let $S$ denote the decimal interval [32, 44]. Refers to Figure 14, when the input string is coming from right to left, we observe the following:

Bit pattern 1 ('100110', the LSB is 0):

Decimal value = 38 $\in S$, translate the 6-bit block and output 38 + 46 ('T').
Bit pattern 2 ('001101'):

Decimal value = 13 \in S,
translate the 5-bit block of '00110' (shift 1 bit left), and output 6 + 46 ('4').

Bit pattern 3 ('111101'):

Decimal value = 61 \notin S,
translate the 5-bit block of '11110' (shift 1 bit left), and output 30 + 46 ('L').

Bit pattern 4 ('100100'):

Decimal value = 36 \in S, output 36 + 46 ('R').

![Figure 14. Bit pattern dissection of translation.](image)

The displacement of 46 above is to map decimal values into the desired ASCII code range ['.', 'Z']. The output characters will be 'T4LR....' and leave the last 2 bits to be the MSB of the next 6-bit block. When the EOF or last byte of buffer is encountered, the remaining bits will be padded with 0s in LSB to form the last pattern. For the example in Figure 14, if '10010001' is the last input byte, then the last 6-bit pattern will be '010000' and translated to '01000' + 46 ('6'), the output is then 'T4LR6'. The inner loop of translation algorithm is listed in Figure 15.
loop: if the scanned 6-bit block is in interval [32, 44]:
    output (6-bit pattern+46);
else
    unget 1 bit and output (5-bit pattern+46);
rebuild bit pattern from remaining bits;
if number of remaining bits >= 6:
    goto loop;
else input next byte;

Figure 15. Translation algorithm.

2. Recovery Algorithm

The displacement of 46 made in translation has to be reset for each input character in recovery at the receiving hosts. If the value after reset is in S, an original 6-bit translated pattern is assumed and a 6-bit block is recovered; otherwise it maps to a 5-bit block. The output characters 'T4LR6'in Figure 14 will be recovered to the original bit string as shown in Figure 16.

Because the file before translation is byte-oriented, the recovery of the last input character should complete the last byte of original compressed/encrypted package. The inner loop of the recovery algorithm is listed in Figure 17.

Translation and recovery algorithms are two separate functions in the verify() routine of main() (listed in Appendix A). In the host system, character set translation is final step before transmission. The program takes each byte from the temporary file built by compression/encryption, and adds 3 bytes header in output file. Each of the 3-byte header, of course is within [46, 91] too. Moreover, the inner loop of translation function.
trans() (See Figure 15), can be designed to incorporate the output buffer of compression/encryption for various compression algorithms. For instance, the variable buffer size in LZW algorithm requires variable loop index \( n \in [9, 13] \).

At the receiving system, recovery operation is proceeded first by examining the file...
header, similar to the encryption operation. The recovery function i.e. recov() shown in Figure 17, provides an option that allows user to modify/update the data package without change the translated format. The translation will be proceeded automatically after modification. Hence, the whole procedure becomes:

recovery \rightarrow [\text{decryption}] \rightarrow \text{modification} \rightarrow [\text{encryption}] \rightarrow \text{translation}.

C. IMPROVEMENT BY PATTERN REASSIGNMENT

In this section, each bit pattern corresponds to output character will be examined, and shows how we can further reduce the translation expansion ratio by suitable reassigns each of them.

1. Unused Patterns in Translation

The translation algorithms discussed in previous sections examines an input 6-bit block and translates it to either a 6 bits or a 5 bits block. Theoretically, when each input pattern is assumed to be equally likely occurred, having compressed and/or encrypted, as discussed in Section 2, the method 3 with expansion ratio 54.6% seems to be an optimized algorithm. Having enumerated all patterns, however, we can further reduce the expansion ratio to less than 50%.

The clue is that certain 5-bit patterns do not appear in practical translation procedure due to the 1 bit shift operation when the 6-bit value is not in $S$ or interval $[32, 44]$. Figure 18 lists all 6-bit patterns with corresponding decimal values and output characters. Notice that in Figure 18 the 5-bit blocks in sets $S_L$ and $S_U$ exhibit redundancies and six patterns do not occur (values in interval $[16, 21]$), for instance, the
first two 5-bit blocks in $S_L$ are both '00000'. The 6 missing patterns are '10000', '10001', '10010', '10011', '10100', and '10101' with corresponding characters '>', '?', '@', 'A', 'B', 'C' respectively. In other words, when use method 3 in Section 2 we are translating 64 6-bit patterns to 39 (45 - 6) characters with 26 of them appear twice and leave 6 characters unused. The effort now is to translate patterns in $S_L$ or $S_U$ in 6-bit block by assigning unused characters to them. Reexamining Figure 18, we can verify that these missing characters in fact did not appear! That is, what we have done in previous section is restricted to 39 characters instead of 45. This observation could lead to the improvement of expansion ratio.

2. Characters Reassignment

We now consider how to use the 6 unused characters. These 6 unused characters may be assigned to the first six unique 6-bit blocks of $S_U$ (from '101101' to '110010'). That is, we can assign these 6 characters to values in [45, 50]. By doing this, the characters originally assigned to interval [45, 50] (4 characters: 'D', 'E', 'F', and 'G') become unused. These four characters can be used to substitute another four 6-bit patterns, say [51, 54] (from '110011' to '110110'). Moreover, the characters 'H' and 'I' correspond to [51, 54] are reassigned to [55, 56]. This recursive characters reassignment may continue until value 57 was assigned when no more unused character. There are $6 + 4 + 2 + 1 = 13$ characters has been reassigned. As shown in Figure 19 through appropriate displacement of +46 (within $S_A$), +30 (within $S'$), or +59 (within $S_U$) we can rearrange all output characters to be contiguous similar to that in ASCII code. The 6-bit patterns '100000' through '111001' (interval [32, 57]) is now assigned to characters

Figure 18. List of 6-bit patterns and corresponding output characters.

>' > ' through 'W'. All other 6-bit blocks (in $S_A$ or $S_B$) still have to be translated in 5-bit block.

3. Expansion Ratio Improvement

The expansion ratio is improved because we increase the probability of translating 6-bit blocks and reduce that of 5-bit blocks. For all 64 possible 6-bit patterns,
### Figure 19. List of 6-bit patterns with new assignments.

We now have 26 patterns that can be translated and 38 patterns have to be translated in 5-bit blocks. The overall expansion ratio is then:

$$\eta = \frac{8 - 6}{6} \left( \frac{26}{64} \right) + \frac{8 - 5}{5} \left( \frac{38}{64} \right) = 0.4917 = 49.17\%.$$  \hspace{1cm} (19)

This expansion ratio shows a 5.42% improvement over the expression (17).
and achieves the specification set by the Navy. Hence, equation (18) can be rewritten as

$$
\eta = (8 - b_1) \frac{P_{b_1}}{b_1} + (8 - b_2) \frac{P_{b_2}}{b_2},
$$

$$
b_1 = \lfloor \log_2 (N) \rfloor, \quad P_{b_1} = \frac{(N - 2^{\lfloor \log_2 (N) \rfloor}) \times 2}{2^{\lfloor \log_2 (N) \rfloor}}
$$

(20)

$$
b_2 = \lfloor \log_2 (N) \rfloor, \quad P_{b_2} = 1 - P_{b_1}.
$$

Where $p_{bi}$ doubles the probability of equation (18) is the observed result from previous discussion. The number of characters assigned to translate each 6-bit block can always result in the same number of unused 5-bit characters; this is true when N varies. To compare with previous analysis, we can plot the expansion ratio vs number of characters for both equation (18) and (20) shown in Figure 20. Refers to Figure 14, the area between two curves is exactly the ratio improved by reassigning the unused characters. It seems that when N is in the range of [32, 64] the expansion ratios are quite satisfactory. Nevertheless, practical operation environment dictates the choice of N. For example, in order to accommodate a set of Morse code communication, the choice of $N = 45$ seems reasonable regardless of expansion ratio. When $N < 16$, it is not practical to perform the character translation since the expansion ratio can be as high as 700%. On the other hand, when $N$ approaches to 256, there is no need for character translation since the source character set and the target character set are equal in size.

The modification of the translation program from that of method 3 to accommodate the observation made in this section is straightforward by adjusting the
partitions for $S_U$, $S$, $S_L$ (Figure 18), to $S_A$, $S'$, $S_u$ (Figure 19).

D. TRANSLATION EXPERIMENTS

Figure 21 shows a short ASCII file that is to be processed through data compression, data encryption, and character set translation (phone numbers are not real). The compressed and encrypted file after character set translation is shown in Figure 22; all characters appeared within '·' and 'Z' as desired (note that, there is no CR nor LF, the file is displayed in multiple lines for readability). Because the original file is small and therefore is resistant to compression; file size in Figure 22 is larger than that of original file.

From the discussion in Section C.3. (Equation (20)), the theoretical compressed and translated file size can be reduced to: $39.3\% \times (1 + 49.17\%) \approx 58.62\%$. This
I was very pleased to receive your draft data compression research proposal dated February 27th. As requested, I am enclosing a detail list of our projected requirements to further assist you in smoothing your proposal and formalizing thesis work on this subject. Please feel free to contact LT Frank at (Comm) (202) 452-6313 or (AV) 911-1313 if additional clarification will be helpful. Thank you for your professional interest in our data compression needs.

Sincerely,

Figure 21. A sample original text file.

Figure 22. After compression, encryption and translation.

improved algorithm has been applied to the same set of testing files used in Table IV with three more "PAK" files. The results are listed in Table IV. Expansion ratios in Table II are consistent with expression (19). The PAK files in "C&R" column are reduced to 58.23%, 59.78%, 58.94%, or 54.76% of original file sizes; these are very close to the theoretical value 58.62%.

The discussion in this chapter assumed that the occurrences of all bit patterns are equally likely in the input to the translation algorithm. This is a reasonable assumption since the input bit patterns are dictated by the pointer values in unknown

IMPROVED TRS.: Improved translation algorithm.

compression/encryption algorithms. When bit patterns are not equally likely the translation algorithm may be more sophisticated but may achieve a better expansion ratio. For example, if a text file to be processed does not require compression nor encryption the expansion ratio of the character set translation should be smaller than the theoretical 49.17% because the first '0' bit and/or the second '0' bit of each input byte may be skipped in the translation process.
V. CONCLUSIONS

Although the key management scheme discussed in this report is perfectly feasible, it is by no means the only or the best possibility. The method employed here allows only for the availability of different keys for different links and hosts but does not differentiate the different functions or activities for which the keys are used. The functions stressed in this study are data compression and character translation; however, the host system is most likely more versatile. Moreover, the transmissions between hosts, remotes and hosts, remotes and remotes, if independent of each other in encryption, may provide much better protection. These important issues could be solved by a key management scheme based on the popular private-key algorithm, DES. This is beyond the scope of this thesis. Nevertheless, its possibilities introduce a worthwhile follow-on research.

Finally, to make all algorithms and source code completely transportable among hardware/operating system environments, the work of error detection and correction becomes an absolute necessity. It is possible to use 'checksum' or CRC techniques to detect transmission errors by attaching $d$ characters to each block of $b$ characters. These $d$ checking characters ($D$) are computed from the $b$ information characters ($B$). Traditional checksum is not capable of locating which byte in $B$ is in error since characters in $B$ may have $b!$ permutations and some permutations may result in the same $D$. To facilitate the error correction we may have to use some non-commutative
operations in the construction of $D$ from $B$. For instance, characters in $B$ are arranged in two matrices and their product is used as $D$. Because matrix multiplication is non-commutative it may be a starting point for character-oriented error detection and correction. Other powerful error correction codes such as R-S (Reed-Solomon codes) are also available for further study.
APPENDIX A. PROGRAM LISTINGS

This is a routine program to determine whether the input file is compressed file, compressed and encrypted file, compressed and translated file, or mixed all of three; the routine will recover, decrypt, or uncompress according to the command line options which given by main().

        fclose( infile );
        return ftype = 3; /* it was a compressed and translated file */
    }
}
else if ( strncmp( identify, encrypted, 3 ) == 0 )
{
    ftype = 2; /* it was a compressed and encrypted file */
    for ( i = 0; i < 11; i++ )
}
The function process_passw() verify the user's password by implemented the "Masterkey" scheme, both user password and service (compressed package) password are decrypt to a 10 digit (long) number by function passw2num(). First, the 10 digit number should not larger than mod number which defined as 2147483641; further, the user's number is computed according to their list of service key, again mod by 2147483641 to compare with services number, return '1' if equal, otherwise let user has another try. Primes number and service list in this function can be modified to allow system expansion and become flexible. Mod number can be changed to a larger number too, which will increase the password complexity. In this experiment, I built a 70 services system, and 8 masterkey user, details was told in Chapter "Multilevel security".

/* 70 prime numbers from 31, each assigned to a service */
