MAGNETIC DEFLECTOR FOR MESONS PRODUCED IN THE 184-INCH CYCLOTRON

By Wolfgang K. H. Panofsky and Ernest A. Martinelli

The artificial production of mesons by means of high energy \( \alpha \)-particles in the 184-inch cyclotron at Berkeley\(^1\) indicated the desirability of making mesons available outside the cyclotron tank in order to make investigations possible by means other than photographic plates inside the tank. A magnetic deflector to draw mesons out into a re-entrant chamber in the cyclotron wall was therefore constructed.

The circulating \( \alpha \)-particle beam strikes a target at a radius of \( 80\frac{1}{2} \) inches from the center of the cyclotron. The magnetic field at the target position is close to 14,000 gauss, so that low energy mesons are unable to leave the cyclotron. The magnetic deflector consists simply of a magnetic shield placed in such a manner that it shields the meson beam and permits it to enter a re-entrant chamber in the cyclotron wall. (Figure 1).

A magnetic shield for this purpose has to meet four requirements: (1) The field in the channel must be sufficiently low to permit exit of the mesons from the field. (2) It must have a sufficiently high geometrical aperture. (3) The shield must not disturb the field at a radius less than target radius. (4) The shield must not interfere with the electrostatically deflected beam\(^2\) in the cyclotron.

The problem of shielding magnetically to a sufficient extent in an external field of 14,000 gauss is made difficult by the saturation of iron. Saturation effects are reduced if the shield is not circular but has its large dimension perpendicular to the field; this will only give a small increase in flux density in the iron relative to the external field. These considerations lead to the choice of a shield approximately an ellipsoid whose smallest axis is parallel to the field. The ellipsoidal shape is superior to any rectangular geometry since corners would saturate and thus not contribute to the shielding while still contributing to the disturbing field.

The ellipsoidal shape can be easily analyzed mathematically for a given magnetization curve of the iron used. Figure 2 shows a theoretical plot of the shielding ratio attainable with an oblate spheroidal shield with a small cylindrical hole inside the spheroid. (For solution of potential problem, see e. g., Smythe, Static and Dynamic Electricity).\(^3\) The curve is computed for cold rolled steel in an external field of 14,000 gauss. Note the rapid improvement of the attainable shielding ratio with increase in axial ratio of the ellipsoid. An axial ratio of 4:1 was chosen here.

The theoretical disturbance in the field due to the ellipsoid is shown in Figure 3 for an ellipsoid of 12 x 3 inch axis. The shield was placed 3\(\frac{1}{2}\) inches from the target radius, thus disturbing the field by approximately 3\(\frac{1}{2}\)\%. This disturbance is compensated by shims supported on the cyclotron poles, in accordance with the method of Powell, et al.\(^4\) A radial experimental field plot and the field corrected by the shims is shown in Figure 4. The position and geometry are also shown in Figure 4.

Owing to the fact that the shielding action of the iron cannot be computed accurately it was necessary to estimate the meson trajectory first, construct a deflector, compute the trajectory and then build a new deflector to conform to the computed trajectory. The final shape of the shield and the position of the meson trajectory is shown in Figure 5. Figure 6 shows the magnetic field in the channel with and without the shield. Owing to the curvature of the trajectory and the ellipsoidal cross section of the shield, the shield is constructed of 12 layers of hot rolled steel plate, flame-cut to proper shape and bolted together. The hole for the trajectory tapers from an initial hole of 1\(\frac{1}{2}\) inches vertical x 1 inch horizontal to 2\(\frac{1}{2}\) x 2\(\frac{1}{2}\) inches square at the exit end. Figure 7 shows the assembled deflector.

The deflector is designed for a central trajectory corresponding to \( B \times p = 147,000 \) gauss-cm, corresponding to an 8.5 Mev \( \mu \)-meson (taking the mass of the \( \mu \)-meson as 215 \( m_0 \)) or a 6.0 Mev \( \pi \)-meson (taking the mass of the \( \pi \)-meson as 286 \( m_0 \)). The deflector will accept beams of vertical divergences of \( \pm 6^\circ \), horizontal divergences of \( \pm 7.2^\circ \)(at central value of energy); the range of momenta accepted is

\[ AECD 2402 \]

Figure 6. Experimental magnetic field as a function of position along meson trajectory through meson deflector.
Figure 7. Photograph of meson deflector in retracted position.
± 12% about the central value.

At this date the deflector has been used only in conjunction with the photographic mesons of detection. With a cyclotron bombardment of $3 \times 10^{-7}$ amp of $\alpha$-particles for 30 minutes the meson yield is about 30 $\pi$ mesons in the edge of a 100 micron emulsion; this corresponds to a total flux of about 500 mesons/minute out of the aperture of the deflector.

The problem of deflecting mesons by means of a magnetic shield was suggested by Prof. L. W. Alvarez. We are greatly indebted to the magnetic measurements group of the laboratory, notably D. C. Sewell and A. J. Hulse for making magnetic measurements and to Prof. Wilson Powell for valuable discussion.
