A rudimentary statistical energy analysis (SEA) can be employed to decipher the functioning of structural fuzzies. A structural fuzzy is a device that, when coupled strongly to a structure, increases the damping of that structure. A structural fuzzy must be endowed with a modal density and structural damping that by far exceeds those of the structure to which it is strongly coupled.
ABSTRACT

A rudimentary statistical energy analysis (SEA) can be employed to decipher the functioning of structural fuzzies. A structural fuzzy is a device that, when coupled strongly to a structure, increases the damping of that structure. A structural fuzzy must be endowed with a modal density and structural damping that by far exceeds those of the structure to which it is strongly coupled.

Room 210
Photonic Center
8 St. Mary's Street
Boston, MA 02215

This report is based on the seminar given at Boston University as stated above. Viewgraphs are presented on the right and comments relevant to that viewgraph are placed on the left. A few of the remarks made by the audience are included without reference. Nonetheless, the author is thankful for these participations by the attendees.
A Note:

Recently a full fledged effort has been launched to develop analyses which yield information transcending that which is issued by SEA. In particular, there are claims that the information issued by SEA in the low and mid-frequency ranges is deemed inadequate for certain response descriptions and noise control purposes. These issues were deliberately forfeited by assumptions imposed during the development of SEA and, therefore, they lie, by definition, beyond the scope of SEA. The assumptions, so conceived, render SEA a more tractable analysis. It is, therefore, impertinent to blame SEA for any inadequacies resulting from these forfeits. Moreover, there are those who interpret the results in the low and mid-frequency ranges by the failure of SEA to yield information that is suppressed apriori in the development of SEA. Yet, by definition, SEA can and will yield the information that it is designed to yield, independent of the frequency range. Notwithstanding that in a given frequency region, the deviation from the mean-value may fluctuate more and more as the violation of the condition of the modal overlap becomes more severe [1,2]. In SEA the mean-value is the fundamental description. Indeed, the very strength of SEA is that it chooses the right thing (details) to be ignorant about as a way to learn something (mean-values). It takes chutzpah to ascertain the in the low and mid-frequency ranges by the apparent failure of SEA to account for phenomena that lie outside its scope. It transpires that the low and mid-frequency ranges are often determined by the failure of those who profess to understand what SEA says is, is!
Revisiting Elements in Statistical Energy Analysis (SEA)
G. Maidanik, NSWCCD (DTMB)

AGENDA

• A brief review of SEA is presented.

• The modifications in SEA due to the influence of strong couplings among the substructures are discussed.

• Some remedial modifications to SEA are heuristically proposed.

• Two noise control problems are described and interpreted in terms of SEA:

1. Control of loss factors (dissipations) in pipe-like structures containing beads. The beads are modeled to be a fluid of low sound speed and of high damping.

2. Control of vibrations by increasing damping and isolation. In particular, a note is taken of the supplementarity of damping and isolation in vibration control.
Mathematical Symbols

Scalar  

\[ v \]

Vector of Rank \( N \)

\[ y = \begin{bmatrix} v_1 \\ v_2 \\ \vdots \\ v_j \\ \vdots \\ v_N \end{bmatrix} = \{v_j\} \]

Transposed

\[ y^+ = \{v_1, v_2, \ldots, v_j, \ldots, v_N\} \]

Complex conjugate  \( y^* = \{v_j^*\} \)

\[ y^+ y^* \equiv \text{a Scalar} ; \quad y^* y^+ \equiv \text{a Matrix} \]

Matrix of Rank \( N \)

\[ Z = \begin{bmatrix} z_{11} & z_{12} & \cdots & z_{1j} & \cdots & z_{1N} \\ z_{21} & z_{22} & \cdots & z_{2j} & \cdots & z_{2N} \\ \vdots & \vdots & \ddots & \vdots & \ddots & \vdots \\ z_{j1} & \cdots & \cdots & z_{jj} & \cdots & z_{jN} \\ \vdots & \vdots & \ddots & \vdots & \ddots & \vdots \\ z_{N1} & \cdots & \cdots & z_{Nj} & \cdots & z_{NN} \end{bmatrix} = (z_{jl}) \]

e.g.,

\[ z_{\sim} = ((z_{jj} \delta_{jl} - z_{jl}(1 - \delta_{jl})) \]

Impedance Matrix Eq.  Admittance Matrix Eq.

\[ z_{\sim} y = F \quad \quad y = y_{\sim} F \]

where symbolically \( y_{\sim} = (z_{\sim})^{-1} \)
Viewgraph 3

The division of a complex structure into constituent substructures is crucial in SEA. Yet, rarely is this division discussed, and specifications for it are rarely laid down. In part, the reluctance stems from the belief that “An arbitrariness (non-uniqueness) in the service of a good approximation is not a vice, it is a useful device” and, in part, apriori rules are difficult to state. In addition, SEA is a function of the frequency (steady state) variable ($\omega$) or the temporal (transient state variable ($t$). The division may, therefore, be dependent on ($\omega$) or ($t$); e.g., a division at ($\omega_1$) may be different from a division at ($\omega_2$) where $\omega_1 \neq \omega_2$. That dependence of the division is seldom discussed but its significance is here recognized. In the final analysis, it turns out that experience is often the best guide to this division. Needless to state, the larger the number of substructures the higher is the frequency at which the fundamental resonance frequency lies, and the higher is the rank of the matrix equation of motion at SEA. Therefore, the higher the number of substructures the higher is the frequency of validity, and the more difficult is the manipulations of the equation of motion. On the other hand, the smaller the number of substructures the more details are suppressed; excessive suppression of details may render the equation of motion moot and without substance.

None of these extremes are happy circumstances. It is hoped, in this connection, that some idea for the appropriate division procedure will emerge in the reading of this report.
Statistical Energy Analysis (SEA)

\[ z(x) \ n(x) = p_e(x) \quad | \quad x \rightarrow \zeta \quad ; \quad t \ or \ \omega \]

\[ z(\zeta) \ n(\zeta) = P_e(\zeta) \]

\[ x = \{x_\alpha\} \]

\[ n(\zeta) = \{n_\alpha(x_\alpha)\} \]

\[ P_e(\zeta) = \{p_{e\alpha}(x_\alpha)\} \]

\[ z(\zeta) = (z_{\alpha\alpha}(x_\alpha)\delta_{\alpha\gamma} - \int dx_\gamma z_{\alpha\gamma}(x_\alpha | x_\gamma)(1 - \delta_{\alpha\gamma})) \]

\( x_\alpha \) is a vector that spans the dimensionality of the \((\alpha)\)th substructure. Thus, if the \((\alpha)\)th substructure is one-dimensional, \( x_\alpha \) is a scalar. If it is two-dimensional, \( x_\alpha \) is a two-vector and if it is three dimensional, \( x_\alpha \) is a three-vector. The dependence of quantities on the time variable \((t)\) or on the frequency variable \((\omega)\) is implicit in this scalar or matrix impedance equation of motion.
A generic division of a complex structure into substructures is represented in Viewgraph (3). The choice of the division must, however, be compatible with the requirement that the self-impedance operator of the substructures; e.g., \( z_{\alpha \alpha} (x_\alpha) \) of the \( (\alpha) \) th substructure, be eigenoperators so that a complete set of orthogonal mode shape functions may be assigned to each substructure; e.g., \( \phi_{\alpha j} (x_\alpha) \) are assigned to the \( \alpha \) th substructure as depicted in Viewgraph (3). In this manner the individual mode shape vectors and the overall mode shape vector may be defined; \( \phi_{\alpha j} (x_\alpha) = \{ \phi_{\alpha j} (x_\alpha) \} \) and \( \phi (x) = \{ \phi_{\alpha} (x_\alpha) \} \), respectively.

The choice for the self-impedance operators and, therefore, for the coupling impedance operators and the mode shape functions is not unique; they may be chosen in a variety of ways, however, each way may be related to the others. With experience the better choices may be identified.
A complex composed of a number of coupled dynamic systems

\[ Z(x) \, v(x) = p(x) \]

\[ x = \{x_\alpha\} \]

\[ \nu(x) = \{\nu_\alpha(x_\alpha)\} \]

\[ p_e(x) = \{p_{e\alpha}(x_\alpha)\} \]

\[ Z(x) = \left( z_{\alpha\alpha}(x_\alpha) \delta_{\alpha\gamma} - \int dx_\gamma z_{\alpha\gamma}(x_\alpha | x_\gamma)(1 - \delta_{\alpha\gamma}) \right) \]

The rank of the equation of motion is equal to \((N)\), the number of dynamic systems in the complex.

The self-impedances; e.g., \(z_{\alpha\alpha}(x_\alpha)\), are eigenoperators in the sense that

\[ z_{\alpha\alpha}(x_\alpha) \varphi_{\alpha j}(x_\alpha) = z_{\alpha j\alpha j} \varphi_{\alpha j}(x_\alpha) ; \]

\[ \Phi_\alpha(x_\alpha) = \{\varphi_{\alpha j}(x_\alpha)\} ; \quad \Phi(x) = \{\Phi_\alpha(x_\alpha)\} \]
Viewgraph 5

Employing the chosen complete and orthogonal sets of mode shape functions, the modal equation of motion may be derived as stated in Viewgraph (5). The rank of this modal equation may be quite large, especially at the higher frequency ranges. Nonetheless, if this equation can be solved for the modal response \((\mathbf{V})\) and the spatial dependence of the mode shape functions is retained, the response \(V_{\alpha}(X_{\alpha})\), of typically the \(\alpha\)th substructure, may be restored and stated as prescribed in Viewgraph (6).
Modal decomposition — removal of the spatial dependence in the equation of motion — modal equation of motion

\[ z = p_e ; \quad z = (z_{\alpha \alpha} \delta_{\alpha \gamma} - z_{\alpha \gamma} (1 - \delta_{\alpha \alpha})) ; \]

\[ z = \{z_\alpha\} ; \quad z_\alpha = \{z_{\alpha ij}\} ; \quad p_e = \{p_{e \alpha}\} ; \quad p_{e \alpha} = \{p_{e \alpha ij}\} ; \]

\[ z_{\alpha \alpha} = (z_{\alpha ij} \delta_{ij}) ; \quad z_{\alpha \gamma} = (z_{\alpha ij} \gamma) ; \]

\[ z_{\alpha ij} \gamma = \int dx_\gamma \int dx_\alpha \varphi_{ij}(x_\alpha) z_{\alpha \gamma}(x_\alpha | x_\gamma) \varphi_{\gamma}(x_\gamma) . \]

The rank of the modal equation of motion is equal to

\[ \sum_\alpha N_\alpha, \text{where } N_\alpha \text{ is the number of all relevant modes in the } (\alpha)th \text{ dynamic system.} \]
Again, the modal equations of motion are stated in Viewgraph (6). Since a set of mode shapes is assumed to be complete and orthogonal, the modes in each substructure are not coupled, couplings occur only between modes belonging to different substructures (dynamic systems).

The inverse equation of motion is stated in order to indicate that if $(z)$ is known, its inverse $(y)$ may be used to directly determine the response vector $(v)$ once the external drive vector $(p_e)$ is given.

The high rank of the impedance matrix or the admittance matrix modal equation of motion may render a solution well nigh impossible. Means to reducing the rank may thus be advantageous, even at the expense of forfeiting details.
Recovery of the spatial dependence

\[ v_\alpha(x_\alpha) = \mathbf{v}_\alpha^\top \cdot \mathbf{\varphi}_\alpha(x_\alpha) \quad ; \quad p_{e\alpha}(x) = \mathbf{p}_{e\alpha}^\top \cdot \mathbf{\varphi}_\alpha(x_\alpha) \]

Thus, if the eigenvectors \( \mathbf{\varphi}_\alpha(x_\alpha) \) are appropriately stored, they can be used in this reconstitution when desired.

Modal equation of motion

\[ \mathbf{\zeta} \cdot \mathbf{v} = \mathbf{p}_e \quad ; \quad \mathbf{\zeta} = (\mathbf{\zeta}_\alpha \mathbf{\delta}_{\alpha\gamma} - \mathbf{\zeta}_{\alpha\gamma}(1 - \mathbf{\delta}_{\alpha\gamma})) \]

\[ \mathbf{\zeta}_{\alpha\alpha} = (\mathbf{\zeta}_{\alpha j} \mathbf{\delta}_{jl}) \quad \quad \mathbf{\zeta}_{\alpha\gamma} = (\mathbf{\zeta}_{\alpha j} \mathbf{\gamma}_l) \]

No modal couplings in a dynamic system

Modal couplings across dynamic systems

\[ \mathbf{\zeta} = \mathbf{\zeta}_e = \{ \mathbf{\zeta}_\alpha \} \quad ; \quad \mathbf{\gamma} = (\mathbf{\zeta})^{-1} \quad ; \quad \mathbf{p}_e = \{ \mathbf{p}_{e\alpha} \} \]
The forfeiting of details starts with the abandonment of spatial information within each substructure; only the response of each mode is registered without heed to its spatial distribution -- the mode is, then, reduced to be a simple harmonic oscillator. Once the spatial information is forfeited, the phase of each harmonic oscillator loses its significance. If forfeiting the phases can be advantaged in the effort to reduce the rank of the modal equation of motion, let it be done. The phases are forfeited by quadratizing the modal equation, as stated in Viewgraph (7). Then, the real part of the resulting equation is executed, again, as stated in Viewgraph (7). The fundamental statement of SEA is presented. This statement is extrapolated from findings pertaining to the interaction between two linear harmonic oscillators [2,3].
Return to the modal equation of motion

\[ \zeta \nu = P e ; \quad \zeta_{\alpha j} \nu_{\alpha j} - \sum_{\gamma} \sum_{q} \zeta_{\alpha j \gamma q} \nu_{\gamma q} (1 - \delta_{\alpha \gamma}) = p e_{\alpha j} . \]

In this equation \( \varphi (x) \) is forfeited by spatial averaging.

Now the phases in \( \nu \) are forfeited by quadratizing the modal equation

\[ \zeta_{\alpha j} |\nu_{\alpha j}|^2 - \sum_{\gamma} \sum_{q} (\nu_{\alpha j})^* \zeta_{\alpha j \gamma q} \nu_{\gamma q} (1 - \delta_{\alpha \gamma}) = (\nu_{\alpha j})^* p e_{\alpha j} . \]

Take the real part of and normalize

\[ \eta_{\alpha j \alpha j} \varepsilon_{\alpha j} - \text{Re} \left( \sum_{\gamma} \sum_{q} (\nu_{\alpha j})^* (\zeta_{\alpha j \gamma q} / \omega)(\nu_{\gamma q})(1 - \delta_{\alpha \gamma}) \right) = (\pi e_{\alpha j} / \omega) \]

\[ + \sum_{\gamma} \sum_{q} \eta_{\alpha j \gamma q} (\varepsilon_{\alpha j} - \varepsilon_{\gamma q}) (1 - \delta_{\alpha \gamma}) \]

This is the fundamental statement of SEA with

\[ \eta_{\alpha j \gamma q} = \eta_{\gamma q \alpha j} = \begin{cases} \text{Small if } \omega_{\alpha j} \neq \omega_{\gamma q} \\ \text{Large if } \omega_{\alpha j} \approx \omega_{\gamma q} \end{cases} \]
The definition of the modal energy ($e_{aj}$) of the $(j)$th mode (harmonic oscillator) in the $(\alpha)$th substructure is stated in terms of the mass ($M_{\alpha}$) of that substructure. The quantity ($E_{Kaj}$) is the kinetic modal energy stored in the referenced mode. The real part of $\{v_{aj}^* p_{ej}\}$ is equated to the external power input into the $(j)$th mode in the $(\alpha)$th substructure.

The span function is defined in terms of a frequency bandwidth ($\Delta \omega$) centered about ($\omega$) that includes all modes within it. Thus, $\langle \cdots \rangle_{\Delta \omega}$ represents frequency averaging over the quantities that pertain to the resonance frequencies that lie within ($\Delta \omega$). In transiting from Equation (a) to (b) on Viewgraph (8), equipartion of modal energy is assumed; namely, $e_{aj} = e_{ai} = e_{i}$ and $e_{\gamma q} = e_{\gamma r} = e_{\gamma}$ of modes that lie within the modal span functions $U_{aj}$ and $U_{\gamma q}$, respectively. Equation (c) on Viewgraph (8), merely generalized Eq. (b) and cast this generalization in matrix form. Note that $\eta_{\gamma \alpha} = \eta_{\alpha \gamma}$ but $\eta_{\gamma \alpha}$ is not necessarily equal to $\eta_{\alpha \gamma}$. Indeed, the two quantities; namely, $\eta_{\gamma \alpha}$ and $\eta_{\alpha \gamma}$, are related by a consistency relationship, as stated in Viewgraph (9).
Modal equation of SEA

\[ \varepsilon_{\alpha j} \approx M_{\alpha} |\nu_{\alpha j}|^2 \approx 2\varepsilon_{K\alpha j} \]

\[ \pi_{\alpha j} = \text{Re}\{\nu_{\alpha j}^* p_{e\alpha j}\} \]

\[ \eta_{\alpha j} = \text{Re}\{z_{\alpha j} / (\omega M_{\alpha})\} \]

Using the modal span functions \( U_{\alpha j}(\omega, \omega_{\alpha j}, \eta_{\alpha j}) \)

\[ \langle \eta_{\alpha j} \varepsilon_{\alpha j} + \sum_{\gamma} \sum \eta_{\alpha j\gamma q} (\varepsilon_{\alpha j} - \varepsilon_{\gamma q})(1 - \delta_{\alpha\gamma}) \rangle = (\pi_{e\alpha j} / \omega) \rangle_{\Delta\omega} , \quad (a) \]

\[ \eta_{\alpha\alpha} \varepsilon_{\alpha} + \sum_{\gamma} \eta_{\gamma\alpha} (\varepsilon_{\alpha} - \varepsilon_{\gamma})(1 - \delta_{\alpha\gamma}) = (\pi_{e\alpha} / \omega) , \quad (b) \]

\[ (\approx \approx) \varepsilon = \pi_{e} ; \quad \eta = (\eta_{\alpha} \delta_{\alpha\gamma} - \eta_{\gamma\alpha}(1 - \delta_{\alpha\gamma})) . \quad (c) \]

\[ \omega = (\omega \delta_{\alpha\gamma}) ; \quad \varepsilon = \{\varepsilon_{\alpha}\} ; \quad \pi_{e} = \{\pi_{e\alpha}\} \]

\[ \eta_{\alpha} = \sum_{\gamma} \eta_{\gamma\alpha} ; \quad \eta_{\gamma\alpha} = n_{\gamma} \eta_{\gamma\alpha} ; \quad \eta_{\gamma\alpha} = \langle \eta_{\gamma q\alpha j}\rangle_{\Delta\omega} \]
Global density quantities are defined in terms of the (typical) modal quantities and the modal densities. The modal density $n_\alpha(\omega)$ of the \(\alpha\)th substructure counts the modes per unit frequency that reside about the frequency \(\omega\). Thus, $n_\alpha(\omega)(\Delta \omega)$ are the number of modes that are spanned within the modal span function. This number is $\langle U_{\alpha j}(\omega, \omega_{\alpha j}, \eta_{\alpha j}) \rangle_{\Delta \omega}$. [cf. Viewgraph (8).] As indicated on the figure, a substructure at SEA is completely defined in terms of its loss factor; e.g., \(\eta_{\alpha\alpha}\) for the \(\alpha\)th substructure, of its modal density; e.g., \(n_\alpha\) for the \(\alpha\)th substructure, of its mass; e.g., \(M_\alpha\) for the \(\alpha\)th substructure* and, finally, of its coupling loss factors; e.g., \(\eta_{\alpha\gamma}\) for the coupling between the \(\gamma\)'th and the \(\alpha\)th substructures. Consistent relationships exist among the coupling loss factors as stated in Viewgraph (9).

* The mass of a substructure, \(M_\alpha\) for the \(\alpha\)th substructure, is seldom stated explicitly, but is always implied.
\[ E_\alpha = n_\alpha \varepsilon_\alpha \quad \text{Stored Energy Density} \]

\[ \Pi_{e\alpha} = n_\alpha \pi_{e\alpha} \quad \text{Input Power (External) Density} \]

\[ (\eta_{\gamma\alpha} / \eta_{\alpha\gamma}) = (n_\gamma / n_\alpha) \quad \text{Consistency Relationship} \]
Viewgraph 10

In Viewgraph (10) a statement of the matrix modal equation of motion and the matrix global equation of motion at SEA are stated. Note the difference between the loss factor matrix $\mathbf{\eta}$ for the modal and the global equations. The difference lies merely in the off-diagonal elements and that difference is accounted for by the consistency relationship stated in Viewgraph (9). The matrices are the transpose of each other.
Modal SEA

$$\eta \sim \varepsilon = \pi_e \ ; \ \varepsilon = \{\varepsilon_\alpha\} \ ; \ \pi_e = \{\pi_{e\alpha}\} \ ;$$

$$\eta = (\eta_\alpha \delta_{\alpha\gamma} - \eta_{\gamma\alpha}(1-\delta_{\alpha\gamma})) \ ; \ \eta_\alpha = \sum_\gamma \eta_{\gamma\alpha} \ ;$$

Global SEA

$$\eta \sim \sim E = \Pi_e \ ; \ E = \{E_\alpha\} \ ; \ \Pi_e = \{\Pi_{e\alpha}\} \ ;$$

$$\eta = (\eta_\alpha \delta_{\alpha\gamma} - \eta_{\gamma\alpha}(1-\delta_{\alpha\gamma})) \ , \ \omega = (\omega \delta_{\alpha\gamma}) \ .$$
Viewgraph 11

A recap is briefly stated in Viewgraph (11).
The spatial dependence in the equation of motion is removed by introducing sets of orthogonal modes: A set of modes per substructure.

The phase dependence is removed by quadratizing linear quantities:

- **Responses** → **Stored Energy Densities**
- **External Drives** → **External Input Power Densities**
- **Dissipations** → **Loss Factors**
- **Couplings** → **Coupling Loss Factors**
- **Sum Over Modes** → **Global Modal Densities**
- **(Quantity)** → **(Δω) (Quantity Density)**
A question may be asked as to whether the external input power density into a substructure; e.g., the \((\alpha)\)th substructure, is affected by the couplings to other substructures. When SEA was developing under the assumption that the coupling strengths are weak; e.g.,

\[ \eta_{\alpha\gamma}(\eta_{\gamma\gamma} + \eta_{\alpha\gamma})^{-1} \ll 1 \]

the external input power density \((\Pi_{\alpha})\) into the \((\alpha)\)th substructure was assumed to be unaffected by the couplings; i.e., it was assumed that

\[ (\Pi_{e\alpha} / \Pi_{e\alpha}^o) \equiv 1 \]

Is this result valid for coupling strengths that are strong? A heuristic argument is developed in an attempt to answer this question.
\[ \Pi_{e\alpha}/\Pi_{e\alpha}^0 = ? \]
For this purpose it is found useful to first define a modal coupling strength ($\xi_\alpha^\gamma$) and its counterpart, a global coupling strength ($\Xi_\alpha^\gamma$). The definitions are cast in proper parametric forms; the modal and the global coupling strengths, ($\xi_\alpha^\gamma$) and ($\Xi_\alpha^\gamma$), respectively, are functional of only those parameters that describe the substructures and the couplings between them. These parametric forms are not functional of the external input power into and/or the stored energies in the substructures. Also, note the natural upper limits on the modal and the global coupling strengths.
It is convenient to define the coupling between the $(\gamma)th$ and the $(\alpha)th$ substructures in terms of a modal coupling strength. This modal coupling strength is designated $(\xi_{\alpha}^\gamma)$ and its expression is:

$$(\varepsilon_\gamma / \varepsilon_\alpha) = \eta_{\alpha\gamma} (\eta_{\gamma\gamma} + \eta_{\alpha\gamma})^{-1} = \xi_{\alpha}^\gamma < 1 .$$

Global coupling strength

$$(E_\gamma / E_\alpha) = (n_\gamma / n_\alpha) \xi_{\alpha}^\gamma = \Xi_{\alpha}^\gamma < (n_\gamma / n_\alpha) .$$
Viewgraph 14

The definitions of the modal and the global coupling strengths are repeated and the notion of weak and strong couplings are explicitly stated.
Modal coupling strength

\[(\varepsilon_\gamma / \varepsilon_\alpha) = \eta_{\alpha\gamma}(\eta_{\gamma\gamma} + \eta_{\alpha\gamma})^{-1} = \xi_\alpha < 1 \quad .\]

Global coupling strength

\[(E_\gamma / E_\alpha) = (n_\gamma / n_\alpha)\xi_\alpha = \Xi_\alpha < (n_\gamma / n_\alpha) \quad .\]

Weak coupling:

\[
\begin{align*}
\xi_\alpha &<< 1 \\
\Xi_\alpha &<< (n_\gamma / n_\alpha)
\end{align*} \quad ; \quad \text{i.e., } \eta_{\gamma\gamma} \gg \eta_{\alpha\gamma} \quad .
\]

Strong coupling:

\[
\begin{align*}
\xi_\alpha &\lesssim 1 \\
\Xi_\alpha &\lesssim (n_\gamma / n_\alpha)
\end{align*} \quad ; \quad \text{i.e., } \eta_{\gamma\gamma} \lesssim \eta_{\alpha\gamma} \quad .
\]
The definition for the external input power density, into an isolated substructure, in terms of the spectral density of the external drive and the conductance is standard. The expression for the conductance in terms of the modal density and the mass of a substructure is also standard. Relying on these standards, the conductance of a coupled substructure is heuristically suggested. Of course, the couplings may alter the modal densities as well as the masses that define the substructure. It is assumed that such alterations are second order effects even when the coupling are strong; i.e., it is assumed that the $n_\alpha$'s and $M_\alpha$'s are robust parameters with respect to couplings. Under this assumption typically the ratio $(G_\alpha / G_\alpha^0)$ may be determined as stated.
External Input Power

\[ G^o_s = \Pi^o_{e\alpha} , \]

\[ G^o = (\pi/2)(n_\alpha / M_\alpha) , \]

\[ G^o_s = \Pi^o_{e\alpha} , \]

\[ G_\alpha = (\pi/2)(n^\prime_\alpha / M^\prime_\alpha) , \]

\[ \Pi_{e\alpha} / \Pi^o_{e\alpha} = (G_\alpha / G^o_\alpha) ? \]

\[ n^\prime_\alpha = [n_\alpha + \sum_{\gamma \neq \alpha} (n_\gamma \xi^\gamma_\alpha)] ; \]

\[ M^\prime_\alpha = [M_\alpha + \sum_{\gamma \neq \alpha} M_\gamma \xi^\gamma_\alpha] \]

\[ (G_\alpha / G^o_\alpha) = [1 + \sum_{\gamma \neq \alpha} (\Xi^\gamma_\alpha)] [1 + \sum_{\gamma \neq \alpha} (M_\gamma / M_\alpha) \xi^\gamma_\alpha]^{-1} . \]
Modifications to the global equation of motion at SEA are, thus, suggested so that the equation may be expressed in terms of the external input power density vector $\Pi_e$ or in terms of the external input power density vector $\Pi_e^O$. The latter input power density is determined when the couplings are removed. How significant is this modification to SEA? Before answering this question, two simple examples in which the modification is insignificant are considered for the record.

In the first, weak coupling is assumed. For this case, weak coupling is defined as

$$\left( \sum_{\gamma \neq \alpha} \xi_{\alpha}^\gamma \right) \ll 1 \text{ and } \left[ \sum_{\gamma \neq \alpha} \left( M_\gamma / M_\alpha \right) \xi_{\alpha}^\gamma \right] \ll 1.$$

Under this definition $R = 1$. 

Viewgraph 16
\((G_\alpha / G_\alpha^o) = [1 + \sum_{\gamma \neq \alpha} \Xi_\alpha^\gamma] [1 + \sum_{\gamma \neq 2} (\overline{m}_\gamma / \overline{m}_\alpha) \Xi_\alpha^\gamma]^{-1}; \overline{m}_\gamma = (M_\gamma / n_\gamma)\)

\((G_\alpha / G_\alpha^o) = \begin{cases} > 1 & \text{modal density-rich couplings} \\ 1 & \text{similar couplings} \\ < 1 & \text{mass-rich couplings} \end{cases}\)

\(\beta E = (\eta \omega) E = \Pi_e = R \Pi_e^o\)

\((\Pi_e / \Pi_e^o) = (G_\alpha / G_\alpha^o)\)

\(G_\alpha^o S_{f\alpha} = \Pi_{e\alpha}^o; \quad G_\alpha S_{f\alpha} = \Pi_{e\alpha}\)

\(R = (R_\alpha \delta_{\alpha\gamma})\); \(R_\alpha = [1 + \sum_{\gamma \neq \alpha} \Xi_\alpha^\gamma] [1 + \sum_{\gamma \neq \alpha} (\overline{m}_\gamma / \overline{m}_\alpha) \Xi_\alpha^\gamma]^{-1}\)

\(\frac{[1 + \sum_{\gamma \neq \alpha} (M_\gamma / M_\alpha) \xi_\alpha^\gamma]}{[1 + \sum_{\gamma \neq \alpha} (M_\gamma / M_\alpha) \xi_\alpha^\gamma]}^{-1}\)
In the second, similar coupling is assumed. In this case

\[(M_\alpha / n_\alpha) = (M_\gamma / n_\gamma) = (M / n) = \bar{m}\]

and, therefore, again \(R = \frac{1}{\bar{m}}\). A physical structure that trivially falls into this category is derived by introducing a “control line” on a plate; the control line is featured by the dashed line. In this example \(n_\lambda \propto A_\lambda; M_\lambda \propto A_\lambda\) and \(\xi' \lambda \rightarrow 1\). Therefore, similar couplings are assured and \((\Pi e_\alpha / \Pi e^0_\alpha) = 1\). A ratio that may be of interest to determine is \((E_\alpha / E^0_\alpha)\). The determination is presented in Viewgraph (17). The results indeed make physical sense and could be apriori predicted.
\[ n_\alpha \propto A_\alpha \quad ; \quad M_\lambda \propto A_\lambda \quad \text{and} \quad \xi_\alpha \to 1 \]

\[ \therefore \quad \text{Similar couplings and} \quad (\Pi_{\epsilon \alpha} / \Pi_{\epsilon \alpha}^o) \to 1 \]

\[ (E_\alpha / E_\alpha^o) = (\eta_{\alpha\alpha} / \eta_t) \; ; \quad \eta_t = [\eta_{\alpha\alpha} + \eta_{\gamma\gamma} (A_\gamma / A_\alpha)] \]

\[ (E_\alpha / E_\alpha^o) = (A_\alpha / A) (\eta_{\alpha\alpha} / \eta_e) \; ; \quad A = A_\alpha + A_\gamma \]

\[ \eta_e = (A)^{-1} \left[ \eta_{\alpha\alpha} A_\alpha + \eta_{\gamma\gamma} A_\gamma \right] \]

\[ (E_\alpha / E_\alpha^o) \simeq \frac{\Pi_{\text{diss}}}{\text{in (}\alpha)\text{th}} / \frac{\Pi_{\text{diss}}}{\text{in [(}\alpha)\text{th}+(\gamma)\text{th}]} \]

If \( \eta_{\alpha\alpha} \approx \eta_{\gamma\gamma} \), \( (E_\alpha / E_\alpha^o) \simeq (A_\alpha / A) \)
What is the relevance of the modified global equation of motion at SEA to its application, say, to a noise control problem? The application is illustrated in Viewgraph 18. In this viewgraph, a substructure; e.g., the \((\alpha)\)th is depicted in isolation and as coupled to another substructure; e.g., the \((\gamma)\)th. The coupling is introduced in order to achieve a noise control goal, as stated in Viewgraph 18. A generic definition of a loss factor is suggested and challenged.
A noise control goal is usually expressed in SEA by a ratio of quantities. Thus, a legitimate noise control goal may be expressed in terms of minimizing \( \frac{E_\alpha}{E_\alpha^o} \).

Some of these ratios are defined as loss factors, i.e.,

\[ \eta = \left[ \frac{\Pi_e}{(\omega E)} \right] ; \quad \text{What } \Pi_e \text{?} \]

\[ \text{What } E \text{?} \]
Viewgraph 19

The generic definition for a loss factor may support a number of definitions. The relationships among these definitions are also presented. All these definitions pertain to loss factors that are of proper parametric forms. Which of these definitions address true loss factors is also noted.

A loss factor requires accounting for the external input power density into a structure (or a substructure) and the generated energy density stored in the structure needs to be totally accounted for. Otherwise, questions such as “Where did the energy go?” may arise in a formalism that is basically a statement of the “conservation of energy.”
\[ \eta_{\alpha\alpha} = \frac{\Pi_{e\alpha}}{\omega E_{\alpha}} \quad ; \quad \eta_{t\alpha} = \eta_{t} = \frac{\Pi_{e\alpha}}{\omega E_{\alpha}} \quad ; \]

\[ \eta_{t\gamma} = \eta_{t\gamma} = \frac{\Pi_{e\gamma}}{\omega E_{\gamma}} \quad ; \quad \eta_{e} = \eta_{e} = \frac{\Pi_{e\gamma}}{\omega E_{\gamma}} \; . \]

\[ E = (E_{\alpha} + E_{\gamma}) \quad ; \quad \Pi_{e\alpha} = \omega [(\eta_{\alpha\alpha} E_{\alpha}) + (\eta_{\gamma\gamma} E_{\gamma})] \; . \]

\[ \eta_{t} = [\eta_{\alpha\alpha} + \eta_{\gamma\gamma} \Xi_{\alpha}] \quad ; \quad \eta_{t\gamma} = \eta_{t} (\Xi_{\alpha})^{-1} \quad ; \]

\[ \eta_{e} = \eta_{t} [1 + \Xi_{\alpha}^{\gamma}]^{-1} \quad ; \quad \Xi_{\alpha}^{\gamma} = (E_{\gamma} / E_{\alpha}) \; . \]

Only \( \eta_{\alpha\alpha} \), \( \eta_{\gamma\gamma} \), and \( \eta_{e} \) are TRUE loss factors.
A practical example is presented in Viewgraph 20. A hollow rectangular steel structure is considered as a master substructure. This substructure is coupled to another. The second substructure is composed of beads that fill-in the hollow space. The beads are modeled as a fluid of low compressibility compared with that of water and density that is comparable with that of water. The low compressibility and the moderate density yield a low sound speed; e.g., in the range of one-fifth of the sound speed in air. The low speed of sound generates high modal densities. The rubbing of beads against their neighbors yield high loss factors in the beaded-fluid. The moderate density allows, nonetheless, for reasonably high coupling strengths. These attributes qualify the beaded-fluid substructure as a structural fuzzy. As such, in the steady state condition, a significant portion of the energy density is stored in the adjunct structure and much of it is efficiently dissipated. In this way the structural fuzzy constitutes an effective damping device; however, at best it yields an overall loss factor that converges on that of the adjunct substructure, as dictated by Le Chatelier’s Principle. Le Chatelier’s Principle roughly states: “When a dynamic system is modified (e.g., by coupling to it a structural fuzzy) with the intention of achieving a high degree of change in the noise it issues, the achievement is mitigated by the implementation of the modification,” e.g., the loss factor converges, at best, to that of the adjunct substructure.
\[ L = (10 \, L_1); \, L_1 = L_2; \, h = (L_1/20) \]

**Le Chatelier's principle**

\[ \left( \frac{E_\alpha}{E_\alpha^o} \right) = \left( \frac{\Pi_{e\alpha}}{\Pi_{e\alpha}^o} \right) \left( \frac{\eta_{\alpha\alpha}}{\eta_t} \right) \]

\[ \eta_t = \left[ (\eta_{\alpha\alpha} + (\eta_{\gamma\gamma} \Xi_{\alpha}^\gamma)) \right] ; \left( \frac{\Pi_{e\alpha}}{\Pi_{e\alpha}^o} \right) \neq 1 \]

\[ \left( \frac{\Pi_{e\alpha}}{\Pi_{e\alpha}^o} \right) = (1 + \Xi_{\alpha}^\gamma) \left[ 1 + \left( \frac{m_\gamma}{m_\alpha} \right) \Xi_{\alpha}^\gamma \right]^{-1} \]

\[ \left( \frac{E_\alpha}{E_\alpha^o} \right) = \left( \frac{\eta_{\alpha\alpha}}{\eta_e} \right) \left[ 1 + \left( \frac{m_\gamma}{m_\alpha} \right) \Xi_{\alpha}^\gamma \right]^{-1} \]

\[ \eta_e = \left[ (\eta_{\alpha\alpha} + \eta_{\gamma\gamma} \Xi_{\alpha}^\gamma) \left[ 1 + \Xi_{\alpha}^\gamma \right]^{-1} \right] \]
The attributes of the combined structure, comprising the master substructure and the adjunct substructure, are exemplified in Viewgraph 21 a and b. The loss factor $\eta_t$, in Viewgraph 21c, is that derived by setting the ratio $(\Pi e^\alpha / \Pi^0 e^\alpha)$ equal to unity. [cf. Viewgraph 20.] The convergence of the overall loss factor onto $\eta_e$ is clearly discernable in Viewgraph 21.
Standard Structure

\[ L = (10L_1); \quad L_1 = L_2; \quad h = (L_1 / 20) \]

a)

\[ \text{Log}_{10}(\text{Modal Density}) \]

\[ \text{Log}_{10}(f) \]

\[ n_\gamma \]

\[ n_\alpha \]

b)

\[ (E_\gamma / E_\alpha) = (\Xi_\gamma) \]

\[ \text{Log}_{10}[\Xi_\gamma] \]

\[ \text{Log}_{10}(f) \]

c)

\[ \text{Log}_{10}(\eta) \]

\[ \text{Log}_{10}(f) \]

\[ \eta_f \]

\[ \eta_e \]

Standard Beads

\[ c_\gamma = 250; \quad (\rho_\alpha / \rho_\gamma) = 10; \quad \eta_{\alpha\alpha} = 0.002; \quad \eta_{\gamma\gamma} = 0.2 \]
Viewgraph 22

Variations on the standard theme are depicted in this Viewgraph; polybeads and beads in the form of sand are exemplified. Again, differentiation between $\eta_l$ and $\eta_e$ is illustrated. The convergence of the loss factor $\eta_e$ on the loss factor $\eta_{\gamma \gamma}$, of the structural fuzzy, is of particular interest.
Poly Beads: $c_\gamma = 200, \quad (\rho_\alpha / \rho_\gamma) = 12, \quad \eta_{\alpha\alpha} = 0.002, \quad \eta_{\gamma\gamma} = 0.2$

Standard: $c_\gamma = 250, \quad (\rho_\alpha / \rho_\gamma) = 10, \quad \eta_{\alpha\alpha} = 0.02, \quad \eta_{\gamma\gamma} = 0.2$

Sand: $c_\gamma = 500, \quad (\rho_\alpha / \rho_\gamma) = 4, \quad \eta_{\alpha\alpha} = 0.002, \quad \eta_{\gamma\gamma} = 0.1$
In this Viewgraph the Principle of Supplementarity of Damping and Isolation is annunciated and formulated. This example is the antonym of that of Structural Fuzzy.
Another noise control goal may be cast in terms of minimizing the ratio of the power density $[(\omega \eta_{\gamma})E_{\gamma}]$ dissipated in the passive ($\gamma$)th substructure to the external input power density ($\Pi_{e\alpha}$) into the externally driven ($\alpha$)th substructure: Example of the Principle of Supplementarity of Damping and Isolation.

The equation is:

$$\omega[(\eta_{\gamma}\alpha)E_{\gamma}) + \eta_{\alpha\alpha}E_{\alpha}] = \Pi_{e\alpha} \quad ; \quad E = (E_{\alpha} + E_{\gamma})$$

$$[(\omega \eta_{\gamma}\alpha)E_{\gamma})]/\Pi_{e\alpha}] = \Xi_{\alpha}[(\eta_{\alpha\alpha}/\eta_{\gamma}\gamma) + \Xi_{\alpha}]^{-1} ; \Xi_{\alpha} = (E_{\gamma}/E_{\alpha})$$

To be minimized

\[ \therefore \text{Increase } (\eta_{\alpha\alpha}/\eta_{\gamma}\gamma) \text{ and decrease } \Xi_{\alpha} \]

Principle of Supplementarity of Damping and Isolation
Viewgraph 24.

In this Viewgraph the Principle of Supplementarity of Damping and Isolation is exemplified and illustrated.
\[
\left[ \frac{(\omega \eta_{\gamma}) E_{\gamma}}{\Pi e\alpha} \right]
\]

Increased damping in the externally driven (\(\alpha\)) th substructure as compared with the damping in the passive (\(\gamma\)) th substructure.

Increased isolation of the passive (\(\gamma\)) th substructure from the externally driven (\(\alpha\)) th substructure.
