Abstract- A finite element muscle model to study the principles of intermuscular myofascial force transmission is developed. The results obtained explain force differences at the distal and proximal tendons of muscles that have mechanical interaction. This is in agreement with experimental findings in other recent studies. The strain distributions found along the fiber direction indicate intermuscular myofascial force transmission. A consequence is that active force generated within one muscle may be exerted at the tendon of another muscle.

Keywords- Finite element method, Intermuscular interactions, Myofascial force transmission, Rat extensor digitorium longus (EDL) muscle

I. INTRODUCTION

Performing the complex task of controlled bodily movements requires the transmission of the force generated by the skeletal muscles onto the skeleton. Although for this transmission, the myotendinous junction is widely accepted to be the major site, rather recently the transmission from the muscle fibers onto the intramuscular connective tissue has been proven to be important as well [1-5]. Referring to this kind of transmission as myofascial force transmission, Huijing [6] suggested that force could be transmitted from the muscle by this path as well (extramuscular myofascial force transmission). Recent experiments revealed significant changes in the length-force characteristics of rat extensor digitorium longus (EDL) muscle on interference with [7] or interactions with the surrounding extramuscular tissues. It was also shown that adjacent muscles interact mechanically [8].

In the present work, the two-domain finite element muscle model described recently [9] is extended to include the principles of intermuscular myofascial force transmission. In experimental work on the subject, the muscle is not accessible for local strain measurements, as it has to remain surrounded by compartmental connective tissues. This modeling study aims at providing such analysis of local strain to enhance understanding of this concept.

II. METHODOLOGY

A 3D-finite element muscle model (linked fiber-matrix mesh model: 1mm model) with a two domain approach was developed [9]. This model consists of two meshes that are linked elastically representing the extracelluar matrix (matrix mesh) and muscle fiber domains (fiber mesh), which occupy the same space. These two meshes are built using earlier developed myofiber or extracellular matrix elements that are introduced into the finite element program ANSYS 5.5.1 as user defined elements. The two meshes are rigidly connected to single layers of elements representing the muscles’ aponeurosis, for which a standard element, HYPER58 from the element library of ANSYS 5.5.1 is used.

III. RESULTS

Isolated EDL Model

The length- total force characteristics of modeled isolated EDL and experimental data [7] are shown in Fig. 2. The model forces are maximally 5% above or below the experimental ones suggesting a fairly good agreement. For the highest lengths considered, the model forces remain high whereas the experimental force decreases with increasing length. This could be due to over estimated passive length-force characteristics of the model as well as the, unrealistic modeling assumption of an initially uniform sarcomere distribution.

Fig. 2. The isometric muscle length-total force curve for isolated rat EDL muscle. Experimental EDL data is adopted from [7]. The muscle force (Fm) is normalized for optimum force (Fmo). Initial muscle length equals 28.7 mm.

Model with Intermuscular Connections

The muscle length-total force characteristics of the lengthened and the restrained muscle, which have intermuscular links between their matrix meshes representing intramuscular collagen is presented in Fig. 3. Note that for distributions of strain and stress in the fiber mesh of the restrained muscle are provided for three lengths of the lengthened muscle (Fig. 4). At \( \Delta l_m = -2.5 \) mm (i.e. both muscles are at the lowest length), the fiber direction strain \( \varepsilon_{22} \) does not exhibit variations, i.e. the lengths of sarcomeres in series within fibers are highly uniform (Fig. 4a). As the lengthened muscle reaches higher lengths \( \Delta l_m = +1.5 \) mm) this homogeneity is replaced by on average 10% longer sarcomeres at the distal end of muscle fibers than at their proximal end.

The consequences of these differences in strain are clearly visible on the fiber direction stresses \( \sigma_{22} \). If both muscles are at low length, the stresses along the fibers of the restrained muscle are rather uniform. As the adjacent muscle is lengthened, distributions of \( \sigma_{22} \) become apparent: at distal ends of fibers approximately 50% higher stresses are encountered than their proximal ends.

For a further assessment of mechanics of interaction between the muscles, the fiber direction strains and stresses within the fiber mesh at the highest length studied (i.e. \( l_m = +1.5 \) mm) are considered for the lengthened muscle of the modeled pair, in comparison to the isolated EDL model (Fig. 5). A clear difference in strain distributions between the two muscles is visible (Fig. 5a). Except for the minor distributions in the most proximal part of the isolated muscle (which is ascribable to the asymmetric EDL muscle geometry), the strains are highly uniform over the whole fiber mesh. In contrast, for the lengthened muscle with intermuscular connections to the restrained muscle, a high level of variation in \( \varepsilon_{22} \) distribution is seen: The sarcomeres along the proximal ends of the muscle fibres are approximately 20%
Muscle force \( F_m \) is normalized for optimum force \( F_{mo} \) of the muscle with intermuscular connections. Although \( \sigma_{22} \) does attain values around unity at certain limited locations, stress values over the major part of the fiber mesh are much lower. As fiber direction stress in the fiber mesh is the dominating factor determining muscle force, this result is highly interesting since the distal forces of the lengthened muscle are higher than that of the isolated muscle throughout the length range and at this particular length (Fig. 6). Such higher forces in spite of the lower mean stresses can only be explained by intermuscular myofascial force transmission from the restrained muscle to the lengthened one.

IV. DISCUSSION

Connective tissue network and force transmission

Muscle can be represented as an extensive 3D set of organized endomysial tunnels, within which the myofibers operate [3]. The identification of intramuscular force transmission from the lateral perimeter surface of myofibers onto the connective tissue network (myofascial force transmission) is relatively recent and limited. However, various studies indicated [1, 3] or experimentally confirmed [1, 3-6, 10] such force transmission and suggested an important functional significance of the connective tissue network. This endomysial network is continuous with the perimysium system and can be regarded as a continuous system of tunnels or tubes as well. In addition, the muscular epimysium is continuous with this system as well as with the connective tissue of adjacent muscles in addition to other elements of the compartment in which the muscles operate [e.g. 5, 7]. Therefore, in vivo there is an additional route for force transmission out of the muscle, which completely bypasses the tendon of the muscle that was the source of the generated force \( F_m \) [5, 7, 11]. In the majority of the earlier work on muscle functioning, muscles are investigated isolated from their surrounding [e.g. 1, 12, 13, 14]. Such a type of experiment eliminates any possible mechanism of inter or extra-muscular force transmission from or to the muscle studied.

Results of the model

The model developed in this study provides the possibility to interpret effects of myofascial force transmission between two maximally activated muscles with a set of elastic links between their matrix meshes representing their intramuscular connections. A finite element muscle model with such an approach is novel. The remarkable result of the analysis is the significant differences between the distal and proximal forces of both of the restrained and lengthened muscles. These differences are in such that for almost all of the length range considered, the distal forces of the lengthened muscle are higher than the proximal forces. This proximo-distal force difference increases with increasing muscle length. For the restrained muscle, the distal force decreases as the lengthened muscle reaches higher lengths. These results are highly compatible with the very recent findings in experimental work exploring intermuscular interaction via myofascial force transmission within rat hindlimb. In their study investigating the effects of blunt dissection and compartmental fasciotomy on rat EDL length-force characteristics, Huijing and Baan [7] showed that a systematic manipulation of the extra and intermuscular connective tissue structures altered proximal EDL force remarkably. These changes were decreases in force and...
changes in the muscle optimum length, as a result of decreased inter and extra-muscular interactions as EDL was dissected further. This indicates the importance of extramuscular connective tissue in force transmission.

The advantage of the present model is its capability to examine the mechanics by analysis of local stress and strain distributions. Such distributions reveal that even though the restrained muscle is fixed at a constant low length, the fiber mesh of the restrained muscle exhibits strain variations along the fiber direction as the second muscle is lengthened (Fig. 4). This is reflected on the fiber direction stresses of the same muscle.

The model results show that such distributions are also present in the lengthened muscle of the adjacent pair (Fig. 5), while the isolated muscle model exhibits highly uniform stress and strain distributions. As mean fiber direction stress within the fiber mesh is considerably lower for the lengthened muscle than for the isolated muscle, the higher distal forces associated with the lengthened muscle indicate that active force generated within one muscle may be exerted at the tendon of another muscle by intermuscular myofascial force transmission. This tendency of 'focusing' of active forces of adjacent muscles on the distal tendon of a distally lengthened muscle is a remarkable conclusion for which further experimental confirmation will be sought in the anterior tibial compartment muscles of rat hind limb.

V. CONCLUSION

Present application of the linked fiber matrix mesh model reveals the principles of the significant role of intermuscular myofascial force transmission on the mechanical behavior of a muscle in an in vivo situation. In agreement with experimental findings, it clearly demonstrates the altered length force characteristics with respect to the isolated situation and increases the understanding of the in vivo mechanics. The conclusion that active force generated within one muscle may be exerted at the tendon of another muscle by intermuscular myofascial force transmission is one of the remarkable results of this analysis.
