Abstract

Structural damage enhanced near-infrared electroluminescence (EL) of a metal-oxide-semiconductor light emitting diode (MOSLED) made on SiOₓ film with buried nanocrystallite Si after CO₂ laser rapid-thermal-annealing (RTA) at an optimized intensity of 6 kW/cm² for 1 ms is demonstrated. CO₂ laser RTA induced oxygen-related defects are capable of improving Fowler-Nordheim tunneling mechanism of carriers at metal/SiOₓ interface. The CO₂ laser RTA SiOₓ film reduces Fowler-Nordheim tunneling threshold to 1.8 MV/cm, facilitating an enhanced EL power of an ITO/ SiOₓ/p-Si/Al MOSLED up to 50 nW at a current density of 2.3 mA/cm².

Index Terms— CO₂ Laser annealing, Si nanocrystal, SiOₓ, Nanotechnology, micro-photoluminescence.
### Title and Subtitle
A Nanocrystallite Si based Metal-Semiconductor-Metal Photosensors and Solar Energy Transformers with Enhanced Responsivity at UV-blue Wavelengths

### Abstract
Structural damage enhanced near-infrared electroluminescence (EL) of a metal-oxide-semiconductor light emitting diode (MOSLED) made on SiOx film with buried nanocrystallite Si after CO2 laser rapid-thermal-annealing (RTA) at an optimized intensity of 6 kW/cm² for 1 ms is demonstrated. CO2 laser RTA induced oxygen-related defects are capable of improving Fowler-Nordheim tunneling mechanism of carriers at metal/SiOx interface. The CO2 laser RTA SiOx film reduces Fowler-Nordheim tunneling threshold to 1.8 MV/cm, facilitating an enhanced EL power of an ITO/ SiOx/p-Si/Al MOSLED up to 50 nW at a current density of 2.3 mA/cm².
I. Introduction

Typically, the synthesis of Si nanocrystals (nc-Si) embedded in plasma enhanced chemical vapor deposition (PECVD)-grown silicon-rich silicon dioxide (SiO$_x$, $x<2$) film for efficient light emission requires a long-term and high-temperature furnace-annealing process (longer than 30 min).\textsuperscript{1-7} This approach meets the difficulty in its compatibility with current integrated-circuits (ICs) processing limit at temperature $<$600$^\circ$C. Furthermore, conventional annealing methods are not possible to \textit{in-situ} anneal a prescribed area on the SiO$_x$ film with $\mu$m scale. CO$_2$ laser based zone annealing (or zone drawing) technique has previously emerged to modify the morphology or structural properties of different materials including polymers, metallic thin films, and superconductors, and dielectrics etc. Particularly, such a laser heating process was also found to initiate the re-crystallization and sintering of ceramic powders, or to enhance the surface crystallinity and the specific phase of an optical nonlinear crystal (beta-BBO). Optical microscopy has shown that the crystallite surface exhibits same morphology as those observed after traditional furnace processing, however, the effect of CO$_2$ laser annealing on the growth rate and the crystallite size is more pronounced. Not long ago, the CO$_2$ laser annealing was primarily employed to improve the properties of a liquid-phase deposited, fluorinated silicon oxide film, which helps to concentrate the fluorinated silicon oxide film and reduce the effective surface charge density caused by surface defect states. Nonetheless, the CO$_2$ laser annealing induced modifications are intensity ($P_{\text{laser}}$) dependent and usually becomes prominent at $P_{\text{laser}} >10$ kW/cm$^2$. Recently, the high-temperature ($>1000$°C) furnace annealing is employed to precipitate the Si nanocrystals in SiO$_2$ film. However, such a high-temperature heat treatment could seriously damages the whole integrated circuits (ICs) on the same Si wafer, which constrains the monolithic integration of the Si nanocrystal doped SiO$_x$ layer with the Si based ICs. Owing to the large absorption coefficient as high as $1.2 \times 10^3$ cm$^{-1}$ of the oxide material at wavelength of 10.6 $\mu$m, a CO$_2$ laser annealing of SiO$_x$ film on quartz substrate is investigated for the first time. In our previous research, the premier demonstration on synthesizing nc-Si in the SiO$_x$ film by CO$_2$ laser rapid thermal annealing (RTA) process has been reported to overcome the aforementioned problems.\textsuperscript{8,9} Later on, Tewary \textit{et al.}\textsuperscript{10} have also demonstrated the locally synthesize light emitting defects and Si nanoparticles in silicon rich oxynitride thin films by using a focused CO$_2$ laser beam with power densities in the range from 0 to 580 W/cm$^2$ and times of 5 s to 60 min. Nonetheless, the CO$_2$ laser annealing SiO$_x$ based light emitting diode has yet not been realized. In this work, we present the fabrication and the
structural/electrical/optical characterization of a metal-oxide-semiconductor light emitting diode (MOSLED), whose oxide layer is the nc-Si embedded SiOₓ film fabricated using a CO₂ laser RTA process. The carrier-transport mechanisms and the electroluminescent (EL) properties of such devices are explored in detail.

II. Experimental

PECVD-grown SiOₓ film was deposited on the p-type (100) Si substrate with a gas mixture of SiH₄ and N₂O. The process temperature, fluence ratio of SiH₄ to N₂O, the rf power, and the reaction gas pressure were 350°C, 1:6, 40 W, and 60 mtorr, respectively. The thickness of PECVD-grown SiOₓ film was 280±10 nm measured by a surface profiler (KLA-Tencor, Alpha-Step 500). Afterwards, the CO₂ laser RTA was performed in atmosphere using a continuous-wave CO₂ laser with ranging from 1.5 to 13.5 kW/cm². The laser spot was focused within 0.2 mm using a hemispherical lens. The CO₂ laser illuminating time was as short as 1 ms. The photoluminescence (PL) of CO₂ laser RTA SiOₓ pumped by a HeCd laser at 5 W/cm² and 325 nm was detected by a fluorescence spectrophotometer (Jobin Yvon, TRIAX-320). Indium tin oxide (ITO) and aluminum (Al) films with thicknesses of 200 nm and 500 nm were used as surface contact and backside contact, respectively. An ITO/SiO₁.₂₅:nc-Si/p-Si/Al MOSLED with a contact diameter of 0.8 mm was made to perform EL. Rutherford back-scattering (RBS) analysis at a detecting angle of 170° under 2 MeV He⁺-ion bombardment and a commercial software of “RAMP” reveals clear Si and O signals at energies of 1.147 MeV and 742.0 keV, respectively. The calculated O/Si ratio of 1.25 corresponds to a total Si concentration of 44.44 atomic%.

The 280-nm thick SiOₓ films were deposited on both-side polished quartz substrates by using high-density plasma enhanced chemical vapor deposition (PECVD) with a gas mixture of SiH₄ and N₂O. The substrate-temperature was kept at 150 °C for 15 min to balance the temperature of the quartz substrate before deposition. The fluence ratio of SiH₄ to N₂O, the rf power and the reaction gas pressure were 1:6, 50 W and 120 mTorr, respectively. Afterwards, the CO₂ laser RTA was performed in atmosphere using a CW CO₂ laser (LTT Corp., ILS-II with a maximum power of 30 W) with \( P_{\text{laser}} \) ranging from 1.5 to 13.5 kW/cm². The laser spot was focused within 0.2 mm² using a hemispherical lens. The CO₂ laser illuminating time was as short as 1 ms. The ablation thickness of SiOₓ film was measured by \( \alpha \)-step with a resolution of 1 nm. The \( \mu \)-PL (or \( \mu \)-PR) of CO₂ laser RTA SiOₓ pumped by
a HeCd laser at 5 W/cm² and 325 nm was detected by a fluorescence spectrophotometer (Jobin Yvon, TRIAX-320). The μ-PR analysis is demonstrated using a similar system with a HeNe laser at wavelength and power of 632.8 nm and 2 mW, respectively. A HRTEM (JEOL, 4000EX TEM) with a point-to-point resolution of 0.17 nm was used to characterize the orientation, lattice constant, size and density of the precipitated Si nanocrystals in SiOₓ film.

III. Results and Discussions

III-1. Surface Temperature Evaluation

During CO₂ laser annealing, the temperature $T(r, z)$ of the annealed SiO₁.₂₅ film is expressed by the following equation:

$$
T(r, z) = \frac{4(1-R)}{\rho C_p} \times \frac{P_{\text{laser}} \tau}{\pi D^2 d_{\text{absorb}}} \times \exp\left(\frac{-4r^2}{D^2}\right) \times \exp\left(-\alpha z\right), \tag{1}
$$

where $r$, $z$, $\tau$, $\rho$ and $C_p$ are the radial distance, the depth, the illuminating time, the density and the specific heat of the SiOₓ film, respectively. $P_{\text{laser}}$ is the illuminating intensity of the CO₂ laser, $R$ is the optical reflectivity of $R=\left[(n-1)^2+k^2\right]/\left[(n+1)^2+k^2\right]$, $r$ is the distance to the center of the focused laser spot, $D$ is the beam diameter at 1/e intensity of the Gaussian distribution, $\alpha$ is the optical absorption coefficient of the SiOₓ film, ($\alpha=4\pi k/\lambda$), $\lambda$ is the laser wavelength, $d_{\text{absorb}}$ is the penetrating depth of the CO₂ laser. The real ($n$) and imaginary ($k$) parts of the refractive index of the SiOₓ film at the wavelength of 10.6 μm in the room temperature are approximately 2.224 and 0.102, respectively. The optical absorption coefficient ($\alpha$), the optical reflectivity ($R$), the Gaussian beam diameter at 1/e intensity ($D$), the radial distance ($r$), the illumination time ($\tau$), the density ($\rho$), and the specific heat ($C_p$) of the SiOₓ film are set as 1209 cm⁻¹, 0.145, 370 μm, 21 μm, 1 ms, 2800 kg/m³ and 1270 J/kg/K, respectively. According to these parameters, the simulated $T_{\text{surface}}$ of the SiOₓ film can be increasing from 130 °C and 3350 °C as the CO₂ laser $P_{\text{laser}}$ enlarges from 1.5 to 13.5 kW/cm². Therefore, the $T_{\text{surface}}$ of the SiOₓ film proportional to the CO₂ laser $P_{\text{laser}}$ is estimated from Eq. (2). For example, the SiOₓ surface temperature profile around the annealed zone under illuminating with the $P_{\text{laser}}$ of 6 kW/cm² at the central part of a Gaussian-beam illuminated zone is about 1349°C. Within an illuminating spot of 400μm diameter, the maximum temperature gradient is only 4.5 °C/μm.

III-2. HRTEM and PL Analysis
After CO\textsubscript{2} laser annealing at laser intensity ($P_{\text{laser}}$) of 6 kW/cm\textsuperscript{2} and furnace annealing at 1100°C for 30 min, broadband near-infrared PL spectra with peak wavelengths of 810 nm and 760 nm as well as spectral linewidths of 106 nm and 135 nm are observed (see Fig. 1(a) and 1(b)), respectively, which are attributed to the emission of nc-Si embedded in SiO\textsubscript{1.25}. The estimated surface-temperature of the SiO\textsubscript{1.25} film at $P_{\text{laser}}$ of 6 kW/cm\textsuperscript{2} was about 1350°C.\textsuperscript{9} The average size of nc-Si buried in CO\textsubscript{2} laser annealed SiO\textsubscript{1.25} is larger than that of furnace-annealed SiO\textsubscript{1.25}, which contributes the decreasing bandgap of nc-Si and the redshift of PL peak wavelength from 760 to 810 nm.\textsuperscript{12} The existence and the size distribution of nc-Si embedded in SiO\textsubscript{1.25} film annealed at $P_{\text{laser}}$ of 6 kW/cm\textsuperscript{2} are confirmed by cross-sectional high resolution transmission electron microscopy (HRTEM) images. HRTEM images reveal that the average diameter of nc-Si is about 5.3 nm. The volume density of nc-Si buried in CO\textsubscript{2} laser annealed SiO\textsubscript{1.25} film is around 1.9 $\times$ 10\textsuperscript{18} cm\textsuperscript{-3}. Another significant PL at 400-650 nm from the CO\textsubscript{2} laser-annealed sample is attributed to incomplete Si precipitation and slight damage of oxide matrix under CO\textsubscript{2} laser annealing within 1ms.\textsuperscript{2,3} Such a phenomenon has never been observed in the furnace-annealed sample since the high-temperature and long-term furnace annealing usually causes a gradual recovery on the compressing strain of the SiO\textsubscript{2} matrix nearby the nc-Si.

As a result, the simulated $T_{\text{surface}}$ of the SiO\textsubscript{x} film can be increasing from 130 °C and 3350 °C as the CO\textsubscript{2} laser $P_{\text{laser}}$ enlarges from 1.5 to 13.5 kW/cm\textsuperscript{2}. At $P_{\text{laser}} = 5.8$ kW/cm\textsuperscript{2} (or $T_{\text{surface}} = 1285$ °C), the cross-sectional HRTEM image reveals that the diameters of Si nanocrystals precipitated in the SiO\textsubscript{x} matrix are ranging from 3 nm to 8 nm, as shown in Fig. 2. The orientation of Si nanocrystals embedded in the SiO\textsubscript{x} film is random, including the (111)-orientation with a lattice spacing of about 0.32 nm. The HRTEM estimated density of
the Si nanocrystals in the CO$_2$ laser RTA SiO$_x$ film at $P_{laser} = 5.8$ kW/cm$^2$ is about $4.5 \times 10^{16}$ cm$^{-3}$. Similar laser re-crystallization was previously demonstrated by using a tightly focused continuous-wave Ar$^+$ laser ($\lambda = 514.5$ nm), which helps to synthesize Si nanocrystals in the hydrogenated amorphous SiO$_x$ (a-SiO$_x$:H) film. It was found that the diameter of the Si nanocrystals increases from 2.5 to 12 nm under an extremely high $P_{laser}$ of ranging from 600 kW/cm$^2$ to 2.6 MW/cm$^2$. However, the surface damage of the a-SiO$_x$:H film was also evidenced at such high intensities even with a short irradiating time. A latter experiment showed similar results by using a frequency-tripled Nd:YAG laser at wavelength and pulsewidth of 355 nm and 8 ns, respectively. By increasing the peak energy density of Nd:YAG laser up to 350 mJ/cm$^2$, the size of Si nanocrystals can be enlarged to 200 nm. Such a process exhibits a similar surface damage problem since the peak $P_{laser}$ of 4.4 MW/cm$^2$ on the sample surface is far beyond the ablation threshold. Gallas et al. then observed that the threshold energy density of a 248 nm-KrF pulsed excimer laser for annealing SiO$_x$ without any ablation is only 85 mJ/cm$^2$. Nonetheless, only a few Si nanocrystals can be precipitated in SiO$_x$ under such low $P_{laser}$, since few laser energies are absorbed and transferred to heat by the SiO$_x$ film with infinitely small absorption coefficient of at such short wavelengths (for example, $\alpha < 1 \times 10^{-6}$ cm$^{-1}$ at $<532$ nm). In contrast, the CO$_2$ laser crystallization can precipitate Si nanocrystals at a $P_{laser}$ of at least 2 orders of magnitude smaller than that required for visible or UV lasers, which simultaneously eliminates the laser-ablation induced surface damage effect. The phase separation between Si and oxygen atoms can be initiated when sufficient energy is absorbed by the SiO$_x$ film, however, the annealing temperature for the precipitation of Si nanocrystals should be higher than 900$^\circ$C. Nesheva et al. have observed the formation of amorphous Si nanoparticles in films annealed at 700$^\circ$C for 1 h. To format the crystallite Si nanocrystals in SiO$_x$ films, a furnace annealing at 1030$^\circ$C for 1 h is mandatory, as confirmed by Raman scattering analysis. In addition, Yi et al. have also demonstrated that the amorphous Si clusters can be formatted at annealing temperature ranging between 300 and 900$^\circ$C, but the crystallization of these amorphous Si clusters is only observed by annealing in a nitrogen atmosphere at $>900^\circ$C for 1 h. That is, the annealing temperature of lower than $<900^\circ$C could not activate the crystallization process for the amorphous Si clusters, even if the annealing duration is lengthened. Under CO$_2$ laser annealing, the surface temperature of the SiO$_x$ film is dependent on the CO$_2$ laser intensity, the lower CO$_2$ laser intensity will reduce the surface temperature of the SiO$_x$ film. Our simulation has also interpreted a threshold annealing
intensity of 4.5 kW/cm$^2$, which corresponds to a surface temperature of 1100°C for initiating the crystallization of the Si nanocrystals. Similarly, the Si nanocrystals are difficult to be precipitated and the size of the Si nanocrystals could not be larger at a lower CO$_2$ laser intensity even with longer exposure times.

**III-3. CO$_2$ Laser Ablation Threshold**

As the CO$_2$ laser intensity was larger than the ablation threshold of SiO$_x$ film (6 kW/cm$^2$), the surface of SiO$_x$ film was sputtered and damaged, which induced oxygen related irradiative defects. The ablation of the SiO$_x$ layer occurs at the CO$_2$ laser annealing of $P_{laser} = 12$ kW/cm$^2$ and leads to another featured PL at 400 nm due to structural damage (see Fig. 1(c)). This results in a concurrent decrease in the near-infrared PL intensity by an order of magnitude, whereas the intensity of blue PL at 400 nm varies oppositely. In fact, the 400-nm PL intensity is increased by one order of magnitude as the $P_{laser}$ increases from 7.5 to 11 kW/cm$^2$, while the surface temperature has already exceeded the melting temperature of fused silica. Curve-fitting of the broadband PL spectrum from 350 nm to 700 nm reveals three peak wavelengths at 415 nm, 455 nm and 520 nm with associated linewidths of 40 nm, 66 nm and 113 nm as well as the associated irradiative defects of weak-oxygen-bond, neutral oxygen vacancy (NOV) defect and $E'_\delta$ center, respectively.$^{2-4}$ Most of these defects are oxygen dependent; and some of them are NOV defects originated from the nc-Si precipitation process as many excessive Si atoms occupied the sites of oxygen move away to precipitate nc-Si. Precipitated nc-Si inevitably compresses the SiO$_x$ matrix and results in the formation of the interstitial oxygen dependent new defects, such as the weak-oxygen bond or ionized oxygen molecule ($O_2^-$).

The corresponding temperature on the SiO$_x$ surface is up to 1902 °C as $P_{laser}$ becomes $>7.5$ kW/cm$^2$, which has already exceeded over the melting temperature of fused silica. Moreover, a CO$_2$ laser annealing process at $P_{laser} > 7.5$ kW/cm$^2$ not only anneals the SiO$_x$ film and precipitates Si nanocrystals locally, but also leads to an increasing of structural damage related PL at 410 nm by at least one order of magnitude. The SiO$_x$ matrix could be promptly compressed during such a rapid laser ablation procedure, where numerous oxygen dependent defects such as weak-oxygen-bond (O-O), oxygen vacancy and ionized oxygen molecule ($O_2^-$) with PL wavelengths at 410-455 nm are generated by the damaged bonds of the SiO$_2$ matrix (see the inset (f)-(g) of Fig. 3). Such a phenomenon was never observed in furnace annealed SiO$_x$ film under a similar condition, as the furnace annealing usually causes a gradual recovery on the compressing strain of SiO$_2$ matrix nearby Si nanocrystals.

7
III-3. EL of CO$_2$ Laser Annealed nc-Si LED

The turn-on voltages of ITO/CO$_2$ laser RTA SiO$_x$/p-Si/Al and ITO/furnace-annealed SiO$_x$/p-Si/Al MOSLEDs are 79 and 87 V with slopes of 2.7 and 2.2 (kV/A/cm$^2$), respectively. Lower turn-on voltage and higher slope of an ITO/CO$_2$ laser RTA SiO$_x$/p-Si/Al MOSLED are attributed to the existence of defects buried in CO$_2$ laser RTA SiO$_x$ film. The electric-field ($E$) dependent emission current ($I$) can be described and the current-field plot can thus be fitted by Fowler-Nordheim (FN) tunneling equations listed as below:\textsuperscript{13}

\[ I_{FN} = A_G A E^2 \exp\left(\frac{-B}{E}\right) , \]  \hspace{1cm} (2)

\[ A = \frac{q^3 (m/m_{ox})}{8\pi\hbar \Phi_B} = 1.54 \times 10^{-6} \frac{(m/m_{ox})}{\Phi_B} \left[ V^2 \right] , \]  \hspace{1cm} (3)

\[ B = \frac{8\pi \sqrt{2m_{ox} \Phi_B}}{3\hbar} = 6.83 \times 10^7 \sqrt{(m_{ox}/m) \Phi_B} \left[ \frac{V}{cm} \right] , \]  \hspace{1cm} (4)

where $A_G$ is the gate area, $E$ is the electric-field, and A and B are usually considered to be constants. $m_{ox}$ is the effective electron mass in the oxide, $m$ is the free electron mass, and $\Phi_B$ is the effective barrier height. The FN tunneling behavior can be confirmed, due to the linear transferred function characteristic in the Arrhenius FN plot (see Fig. 2).

\[ \text{CO}_2 \text{ Laser RTA} \quad \cdot \quad \text{Furnace Annealing} \]

The threshold electric-fields to initiate FN tunneling for CO$_2$ RTA and furnace-annealed MOSLEDs are 1.8 and 3.2 MV/cm, respectively, which indicates that the effective potential barrier of the sample becomes smaller with the assistance of defects. This essentially corroborates with the reduction on threshold electric-field of FN tunneling occurred in the CO$_2$ laser RTA sample. The gradient of power-current (P-I) plot of ITO/CO$_2$ laser RTA
SiOₓ/p-Si/Al and ITO/furnace-annealed SiOₓ/p-Si/Al MOSLEDs are 33.5 and 17.6 (μW/A/cm²), respectively (see Fig. 3). The EL power of the ITO/CO₂ laser RTA SiOₓ/p-Si/Al MOSLED with oxygen-related defects can be enlarged by two times as compared to that of the ITO/furnace-annealed SiOₓ/p-Si/Al MOSLED with a higher turn-on voltage.

The barrier height of ITO-SiOₓ junction is 3.7 eV with electric affinities of 4.7 eV for ITO and 1 eV for SiO₂. The electric affinity and bandgap of Si substrate are 4 eV and 1.12 eV, respectively. Due to the CO₂ rapid-laser-annealing process introduces oxygen-related defects buried in the ITO/CO₂ laser RTA SiOₓ/p-Si/Al MOSLED, these oxygen-related defects and interfacial states facilitate the carrier transport into nc-Si for the electron-hole pair recombination (see the inset of Fig. 3), and also decrease the turn-on voltage. This also elucidates the significant reduction of threshold electric-field of the ITO/CO₂-laser-RTA SiOₓ/p-Si/Al MOSLED. In contrast to the conventional furnace-annealed MOSLED, the high-temperature and long-term furnace-annealing usually causes a gradual recovery on the compressing strain of the SiO₂ matrix nearby the nc-Si and also contributes a defect-free furnace-annealed SiOₓ film, corresponding to the higher turn-on voltage, lower EL power and the difficulty of carrier injection into nc-Si. Consequently, the electrons require a higher electric-field to tunnel through the barriers of the MOS structure. Furthermore, the enhanced P-I slope and EL power from the CO₂ laser RTA SiOₓ based MOSLED are due to the assistance of carrier injection via oxygen-related defects as compared to those of the furnace-annealed SiOₓ based MOSLED at same biased condition.
Nc-Si related EL spectra of ITO/CO$_2$ laser RTA SiO$_x$/p-Si/Al MOSLED with a bright color far-field pattern was decomposed into three luminescent peaks at 590, 715 and 810 nm with the spectral linewidths of 203, 117 and 54 nm as well as peak ratios of 1.65:1.47:1, respectively (see the lower of Fig. 4). The luminescent peaks at 590 and 810 nm emitting from different size of nc-Si were observed, however, the luminescent peak at 715 nm was not obviously found in the PL spectrum. Because of oxygen-related defects, such as weak-oxygen-bond and NOV defects, behave high energy bandgaps, carriers favor to inject into smaller nc-Si with higher energy bandgaps and approximate excited level via oxygen-related defects, and then recombine in the nc-Si. This result corresponds to the largest decomposed-EL intensity at 590 nm and the reduction of the decomposed-EL intensity as the increasing size of nc-Si. Hence, the EL emission from nc-Si at 715 nm can be enhanced and observed. The EL spectrum of ITO/furnace-annealed SiO$_x$/p-Si/Al MOSLED, biased at higher electric-field without the carrier-transport assistant of oxygen-related defects, reveals a deep-red far-field pattern (see the upper inset in Fig. 4) and dual luminescent peaks at wavelengths of 625 and 768 nm with spectral linewidths of 189 and 154 nm, respectively. The EL component at longer wavelength coincides well with that of PL, revealing that the nc-Si-related PL and EL are attributed to the same carrier recombination mechanism. The mechanism of secondary EL peak expanded to shorter-wavelength region (500-700 nm) is possibly attributed to the cold-carrier-tunneling process under appropriate bias. Since the band bending becomes serious under an extremely high electric-field, leading to the carriers between adjacent nc-Si tunneled from first-order quantized state (n=1) to second-order quantized state (n=2), providing a higher population in the second-order state as well as an enhanced spontaneous emission at larger energy.
IV. Achievements and Conclusions

In conclusion, the enhanced near-infrared EL of an ITO/CO₂ laser RTA SiOₓ/p-Si/Al MOSLED is preliminarily demonstrated. The CO₂ laser RTA performs the in-situ and localized temperature control of the SiOₓ film, which thus facilitates precipitating Si nanocrystals from damaging the nearby devices. The equivalent temperature of the SiOₓ surface is increasing from 130°C to 3350°C as the CO₂ laser $P_{\text{laser}}$ enlarges from 1.5 to 13.5 kW/cm². Dense nc-Si can be synthesized in the SiO₁.₂₅ film by using CO₂ laser RTA at $P_{\text{laser}}$ of 6 kW/cm² for 1 ms. The Si nanocrystals with maximum diameter and density of 8 nm and $4.5 \times 10^{16}$ cm⁻³, respectively, can be locally precipitated within the CO₂-laser RTA SiOₓ film, giving rise to a near-infrared PL at 790-806 nm. The comparison on PL spectra of CO₂ laser annealed and furnace-annealed PECVD-grown SiO₁.₂₅ samples reveals the contribution of oxygen related defects. Since the CO₂ laser annealing time is only 1 ms and much shorter than furnace-annealing time (3 hours), the annealing time is insufficient for precipitating larger-size nc-Si, whereas the oxygen-related defects are generated in the CO₂ laser annealed SiOₓ film. These are obtained at just below ablation-threshold intensity (6 kW/cm²), which is at least 2 orders of magnitude smaller than that required for visible or UV lasers. The power dependent μ-PL analysis indicates that the precipitation of small-size Si nanocrystals is initialized when $P_{\text{laser}} > 4.5$ kW/cm² and a maximum PL peak wavelength of 825 nm can be observed at $P_{\text{laser}} = 7.5$ kW/cm².

Nonetheless, the SiOₓ film is ablated with a linear ablation slope of 35 nm/kW/cm² at beyond threshold $P_{\text{laser}}$ of 6 kW/cm². The μ-PR results indicate that the refractive index of the CO₂ laser RTA SiOₓ film varies from 1.57 to 1.87 as the $P_{\text{laser}}$ increases from 1.5 to 7.5 kW/cm². At the $P_{\text{laser}} < 3$ kW/cm², the change in refractive index is less than 0.6% since the precipitation of Si nanocrystals has not yet been initiated. The refractive index of SiOₓ reaches maximum as the surface temperature increases to 1285°C, while the average diameter of Si nanocrystal is also the largest. Annealing at higher intensities not only damages the SiOₓ structure, but also constrains the precipitation and Si nanocrystals and decreases the refractive index of the SiOₓ. This eventually degrades the near-infrared PL and reduces the refractive index of the CO₂ laser RTA SiOₓ film. These defects enhance the carrier transport through the MOSLED, reducing the tunneling threshold from 3.2 to 1.8 MV/cm as compared to the furnace-annealed sample. The elucidation on the role of the oxygen-related defects played on the improved carrier transport and enhanced light emission properties is
addressed. A maximum EL power of nearly 50 nW from the ITO/CO₂ laser RTA SiOₓ/p-Si/Al MOSLED under a biased voltage of 85 V and current density of 2.3 mA/cm² is reported to date.
