The views, opinions and/or findings contained in this report are those of the author(s) and should not be construed as an official Department of the Army position, policy or decision unless so designated by other documentation.
Despite recommendations to increase the cultural sensitivity of genetic counseling, such programs have not been developed or evaluated. The objectives of this study were to develop a Culturally Tailored Genetic (CTGC) protocol for African American women and evaluate its impact on decision-making and satisfaction about BRCA1/2 testing, quality of life, and cancer control practices. With the support of this award, we have developed a comprehensive body of empirical knowledge on genetic counseling and testing among African American women. Our work has evaluated responses to CTGC versus SGC, identified predictors of test result acceptance, and assessed outcomes of genetic counseling among African American women at increased risk for hereditary disease. Importantly, we have developed a method for addressing cultural beliefs and values related to cancer prevention and control in a medically underserved population.
A. INTRODUCTION

Five to 10% of all breast cancer cases have been attributed to two breast-ovarian cancer susceptibility genes called BRCA1 and BRCA2 (BRCA1/2). Genetic counseling and testing for BRCA1/2 mutations is now available through clinical research programs using standard counseling protocols. The goal of pre-test counseling is to facilitate informed decision making about whether to be tested and to prepare participants for possible outcomes. The goal of post-test counseling is to provide information about risk status, recommendations for surveillance, and options for prevention. However, African American and Caucasian women differ in their attitudes about and responses to pre-test education and counseling. Increasingly, cultural beliefs and values are being recognized as important factors in genetic counseling. Despite recommendations to increase the cultural sensitivity of breast cancer risk counseling, such programs have not been developed or evaluated. Therefore, the purpose of this study is to develop a Culturally Tailored Genetic Counseling (CTGC) protocol for African American women and evaluate its impact on psychological functioning and health behaviors compared with Standard Genetic Counseling (SGC) in a randomized clinical trial. This research is linked with Dr. Hughes' Career Development Award and has the following primary technical objectives:

(1) To evaluate the relative impact of CTGC vs. SGC on decision-making and satisfaction about BRCA1/2 testing. Compared to SGC, CTGC will lead to higher rates of test acceptance and satisfaction with testing decisions. These effects will be mediated by increases in perceived benefits and decreases in perceived limitations and risks of genetic testing.

(2) To evaluate the impact of CTGC vs. SGC on quality of life and health behaviors following BRCA1/2 testing. Compared to SGC, CTGC will lead to larger decreases in general and cancer-specific distress, greater increases in adherence to cancer screening guidelines, and lower rates of prophylactic surgery. Reductions in psychological distress will be mediated by increased use of spiritual coping strategies.

Secondary Aim

To identify African American women who are most and least likely to benefit from CTGC vs. SGC. We predict that the relative benefits of CTGC will be greatest for women with greater endorsement of African American cultural values and those identified as BRCA1/2 carriers.

B. BODY

The research was initiated at the Georgetown University Medical Center in 2000 and was transferred to the University of Pennsylvania Medical Center in February 2002. Approval for the use of human subjects was granted in February 2003. During the project period, our efforts focused on (1) subject recruitment, (2) completing genetic counseling and education sessions, (3) completing follow-up telephone interviews, (4) generating peer-reviewed manuscripts, and (5) presenting findings from the research at national scientific conferences.
Subject Recruitment. Eligible subjects were African American women ages 18 and older who had a 5%-10% prior probability of having a BRCA1/2 mutation based on their personal and family history of breast and/or ovarian cancer. Eligible subjects were identified by referrals from mammography and oncology clinics located at the University of Pennsylvania and through a community-based referral network that was developed specifically for the study. Following referral, eligible women were mailed an invitation letter that included information about the purpose of the study and a reply card for women to return if they were not interested in participating. Women who did not return a reply card declining study participation were contacted by telephone to complete a structured baseline telephone interview. This interview took approximately forty minutes to complete and obtained sociodemographic characteristics and personal and family history of cancer and also evaluated risk perceptions, psychological functioning, and health behaviors. Following completion of the baseline telephone interview, eligible subjects were invited to participate in pre-test education and counseling. Those who agreed to participate in this session were randomly assigned to receive Standard Genetic Counseling (SGC) or Culturally Tailored Genetic Counseling (CTCG). Written informed consent was obtained for participation in pre-test education and counseling. After completion of the pre-test education session, subjects who were interested in genetic testing for BRCA1/2 mutations were given an opportunity to consider their decision further and had an opportunity to meet individually with a medical oncologist. Following the meeting with the medical oncologist, blood was drawn for genetic testing after obtaining written informed consent. Once BRCA1/2 test results were available, test results were disclosed using the protocol that was consistent with the format used to provide pre-test education and counseling (SGC or CTCG). Regardless of decisions about genetic testing, women were contacted for 1-, 6-, and 12-month follow-up telephone interviews to re-assess psychological functioning and satisfaction with testing decisions.

Accrual and Response Rates. A total of 335 eligible subjects were identified during the project period and of these, 204 (61%) completed the baseline telephone interview and enrolled in the study, 68 (20%) declined to participate in the study, and 63 (19%) could not be reached after multiple attempts.

Genetic Counseling and Education. Of the 204 women who enrolled in the study, 181 accepted the invitation to participate in genetic counseling and 87 (48%) were randomized to culturally tailored genetic counseling (CTGC) and 94 (52%) were randomized to standard genetic counseling (STGC). Of the women who accepted the invitation to participate in genetic counseling, 104 (57%) completed counseling. Of the 104 women who participated in genetic counseling, 60 (58%) had genetic testing and 52 have received BRCA1/2 results. Retention in follow-up telephone interviews was as follows: 73% retained in the 1-month follow-up, 66% retained in the 6-month follow-up, and 63% retained in the 12-month follow-up.

Selected Research Results

Rates and Predictors of Enrollment in Cancer Genetics Research. We used a comprehensive approach to evaluate the impact of culturally tailored versus standard genetic counseling on decisions about genetic testing and the impact of genetic risk information on health behaviors and psychological functioning among African American women. For example, since African
Americans may be unwilling to participate in cancer genetics research, we first evaluated rates and predictors of enrollment in genetic counseling research in African American women at increased risk for hereditary breast cancer. Our research was the first to provide empirical evidence of the association between decisions to enroll in cancer genetics research and environmental factors. Specifically, we found that most African American women are likely to enroll in genetic counseling research; however, enrollment decisions vary based on the environmental setting from which women are recruited (e.g., oncology facility, general medical practice, community oncology resources). Compared to women recruited from general medical practices, those who were recruited from oncology settings and community oncology resources were about three times more likely to enroll in the study. In addition, women who had a stronger family history of breast or ovarian cancer were most likely to enroll in the study.

Impact of Genetic Counseling on Acceptance of BRCA1/2 Test Results. According to theoretical models of health behavior, intentions are an important antecedent to actual health behaviors. Although previous research has evaluated intentions to have genetic testing among African American women at low risk for having a BRCA1/2 mutation and those from a single BRCA1 kindred, empirical data were not available on genetic testing intentions among African American women at moderate and high risk for having a BRCA1/2 mutation. Our research was the first to evaluate testing intentions in this population. We found that while perceptions of the benefits of genetic testing were high, only about 30% of women reported that they would definitely have genetic testing. Consistent with testing intentions, only 22% of all women who enrolled in the study received BRCA1/2 test results. There was no difference in test result acceptance among women who were randomized to culturally tailored or standard genetic counseling. However, among women at high risk for having a BRCA1/2 mutation, those who were married and women who were less certain about their risk of developing cancer were most likely to receive BRCA1/2 test results. These findings suggest that testing behaviors are likely to be consistent with intentions. In addition, it may be important to emphasize the possibility that BRCA1/2 test results may not provide definitive information about cancer risks during pre-test counseling with African American women to ensure informed decision-making about testing.

Satisfaction with Genetic Counseling. Although satisfaction is an important indicator of the quality of health care services, empirical data were not available on perceptions of satisfaction with genetic counseling for BRCA1/2 mutations specifically among African American women at increased risk for hereditary breast cancer. We found that the majority (96%) of women were very satisfied with genetic counseling overall. Despite this, only 22% of women strongly agreed that the counselor lessened their worries and 26% reported that the counselor helped them to cope better. Women who received culturally tailored genetic counseling were significantly more likely than those who received standard counseling to report that their worries were lessened. These findings suggest that discussion of cultural beliefs and values during genetic counseling may be beneficial to African American women.

Retaining African American Women in Cancer Genetics Research. Retention is a critical component of longitudinal research; however, limited empirical data are available on retention of African American women in cancer genetics research. We evaluated rates and predictors of retention in cancer genetics research among African American women at increased risk for having a BRCA1 and BRCA2 (BRCA1/2) mutation. Participants were African American
women (n=192) at increased risk for hereditary breast-ovarian cancer who were enrolled in a longitudinal genetic counseling research study. Retention was evaluated separately for the 1- and 6-month follow-ups and in terms of overall retention (e.g., completion of both telephone interviews). Women were not provided with a financial incentive for completing follow-up telephone interviews. Seventy-three percent of women and 65% of women were retained at the 1- and 6-month follow-ups respectively; in terms of overall retention, 60% of women were retained in both follow-up telephone interviews. Predictors of retention at 1-month included being employed (OR=2.47, 95% CI=1.24, 4.93, p = 0.01) whereas predictors of overall retention included having a personal history of breast and/or ovarian cancer (OR=2.06, 95% CI=1.07, 3.95, p=0.03) and having completed genetic counseling (OR = 2.63, 95% CI = 1.39, 4.98, p = 0.003). These findings demonstrate that most African American women will be retained in genetic counseling research, especially if concrete services are provided as part of study participation.

C. KEY RESEARCH ACCOMPLISHMENTS

- Produced a comprehensive body of empirical research on genetic counseling and testing among African American women; published 17 manuscripts in this area and presented 23 invited lectures and presentations and national scientific conferences.
- Enrolled the largest cohort of African American women at increased risk for hereditary breast cancer in a prospective randomized clinical trial.
- Determined that most African American women are willing to participate in genetic counseling research.
- Identified predictors of participation in genetic counseling research among African American women.
- Identified factors that influence acceptance of genetic testing and BRCA1/2 test results among African American women.
- Evaluated the effects of culturally tailored versus standard genetic counseling on BRCA1/2 testing decisions and satisfaction.

Professional Development Supported by this Award

Chanita Hughes Halbert, Ph.D., Promoted from Assistant Professor to Associate Professor (with Tenure), Department of Psychiatry, University of Pennsylvania, July 2007.
In addition to being promoted to Associate Professor, Dr. Hughes is now developing a Center for Community-Based Research and Health Disparities in the Department of Psychiatry. She continues to play a leadership role in the Abramson Cancer Center (ACC) and participates on the Strategic Planning Committee for the ACC. Approval to develop the Center for Community-Based Research and Health Disparities was based in part on Dr. Hughes’ productivity and scholarship on this award. As shown above, Dr. Hughes received four independent, peer-reviewed grants based on the results from this award.

**Susan Domchek, MD,** Promoted from Assistant Professor to Associate Professor, Department of Medicine, University of Pennsylvania, July 2007.

**Sarah Charles, MS,** Received Master’s of Science degree in Genetic Counseling from Arcadia University, 2006 and received the 2006 Beth Fine Kaplan Student Award Abstract from the National Society of Genetic Counselors (NSGC) for her thesis project on “Satisfaction with Genetic Counseling among African American Women.” The Beth Fine Kaplan award is the highest student award given by the NSGC.

**E. CONCLUSIONS**

The purpose of this study was to develop a culturally tailored genetic counseling (CTGC) protocol for African American women and evaluate the relative effects of CTGC versus standard genetic counseling (SGC) on BRCA1/2 testing decisions and satisfaction. To our knowledge, this study is the first randomized trial to compare the effects of CTGC versus SGC on testing decisions and outcomes in African American women at increased risk for having a BRCA1/2 mutation. We did not find differences in test result acceptance between women who were randomized to CTGC or SGC. However, women who received CTGC reported greater satisfaction with counseling compared to those who received SGC. These findings suggest that CTGC may be beneficial to African American women even if it does not lead to greater rates of test result acceptance relative to SGC. We also found that a limited proportion of African American women will undergo genetic testing and receive BRCA1/2 test results; however, women who were married and those who were less certain about their risk of developing breast cancer were most likely to receive BRCA1/2 test results. Our research provides novel empirical data on factors that are likely to be important to decisions about genetic testing among African American women. Importantly, we have developed a method for addressing cultural beliefs and values related to decisions about genetic testing among African American women with the support of this award. The method we created can be applied to develop culturally tailored protocols for other types of decisions about strategies for cancer prevention and control among African Americans as well as other populations.

Although effective strategies for recruitment and retention are critical to genetic counseling research, limited empirical data was available on methods for recruiting and retaining African American women in this type of research. Our study was the first to identify predictors of enrollment and retention in genetic counseling research among African American women at increased risk for hereditary breast cancer. We found that the recruitment site is a critical factor in identifying women who are eligible to participate in genetic counseling protocols and may
also be important to decisions about enrolling in genetic counseling research. We also found that while provision of financial incentives may not be necessary to retain African American women in genetic counseling research, provision of concrete clinical services may facilitate retention. The results from our work can be applied to enhance enrollment and retention of African Americans in other types of cancer genetics research.

In summary, through this award, we have generated a comprehensive body of empirical knowledge on genetic counseling and testing for BRCA1/2 mutations among African American women.

Recruiting African American Women to Participate in Hereditary Breast Cancer Research
Chanita Hughes Halbert, Kiyona Brewster, Aliya Collier, ChaChira Smith, Lisa Kessler, Benita Weathers, Jill E. Stopfer, Susan Domchek, and E. Paul Wileyto

ABSTRACT
Purpose
This study evaluated the process of recruiting African American women to participate in genetic counseling research for \( \text{BRCA1} \) and \( \text{BRCA2} \) (\( \text{BRCA1/2} \)) mutations with respect to referral, study enrollment, and participation in genetic counseling.

Patients and Methods
African American women (\( n = 783 \)) were referred for study enrollment.

Results
Of 783 referrals, 164 (21%) women were eligible for enrollment. Eligible women were most likely to be referred from oncology clinics (44%) and were least likely to be referred from general medical practices (11%; \( \chi^2 = 96.80 \); \( P = .0001 \)). Overall, 62% of eligible women enrolled onto the study and 50% of enrollees completed genetic counseling. Women with a stronger family history of cancer (odds ratio [OR] = 3.18; 95% CI, 1.36 to 7.44; \( P = .01 \)) and those referred from oncology clinics and community oncology resources (OR = 2.97; 95% CI, 1.34 to 6.58; \( P = .01 \)) were most likely to enroll onto the study. Referral from oncology clinics was associated significantly with participation in genetic counseling (OR = 5.46; 95% CI, 1.44 to 20.60; \( P = .01 \)).

Conclusion
Despite receiving a large number of referrals, only a small subset of women were eligible for enrollment. Oncology settings were the most effective at identifying eligible African American women and general medical practices were the least effective. Factors associated with enrollment included having a stronger family history of cancer and being referred from oncology clinics and community oncology resources. Referral from oncology clinics was the only factor associated significantly with participation in genetic counseling for \( \text{BRCA1/2} \) mutations.

INTRODUCTION
Despite intensive efforts, African American participation in cancer research remains limited.\(^1\)\(^-\)\(^4\) In addition, African American enrollment in research on \( \text{BRCA1} \) and \( \text{BRCA2} \) (\( \text{BRCA1/2} \)) mutations is low.\(^5\)\(^,\)\(^6\) Recruitment for these studies is a complex process that begins with identifying potentially eligible participants from referral sites, inviting eligible individuals to enroll onto the study, and completing enrollment and study procedures.\(^7\)\(^,\)\(^8\) Little is known about the process of recruiting African Americans to participate in clinical research for \( \text{BRCA1/2} \) mutations or factors that influence outcomes at each stage of the process. The goals of this study were to determine the proportion of women who are referred to a \( \text{BRCA1/2} \) genetic counseling research program who were...
eligible for participation; determine the proportion of eligible women who enroll onto the study; determine the proportion of women who participate in genetic counseling; and evaluate the role of referral site and participant characteristics on each phase of the recruitment process.

Study Population
This study was approved by the Institutional Review Board at the University of Pennsylvania. To be eligible for participation, women had to self-identify as being African American or black, be at least 18 years of age, and have a minimum 5% to 10% prior probability of having a \( BRCA1/2 \) mutation. Participant recruitment was initiated in February 2003. To be included in the analysis of study enrollment, potential participants had to have a defined eligibility status, and if eligible, had to have been contacted about enrollment.

Procedures
Potential participants were identified through a referral network that included seven clinical institutions and community oncology resources (eg, breast cancer support groups, health fairs) located in Philadelphia, PA. At all clinical referral sites, the following information was provided in brochures and flyers given to all African American women by physicians and clinic staff: a new research program specifically for African American women was initiated in February 2003. To be included in the analysis of study enrollment, potential participants had to have a defined eligibility status, and if eligible, had to have been contacted about enrollment.

Eligibility Variables
Clinical factors. Age, personal history of breast and/or ovarian cancer, and family history of cancer were obtained by self-report at referral. Because it is standard practice in genetic counseling to construct a three-generation pedigree, we calculated the total number of first-, second-, and third-degree relatives affected with breast and/or ovarian cancer. Women were categorized as having two or more, or less than two affected relatives.

Recruitment Variables
Referral site. Women were categorized as being referred from oncology resources (eg, oncology clinics [ONCs], mammography facilities), general medical resources (eg, internal medicine, obstetric/gynecology practices), or community oncology resources based on the setting from which they were referred.

Referral personnel. Women were categorized as having been referred to the study by physicians or clinic/research staff.

Participant Characteristics
Sociodemographics. Marital status, education level, employment status, and income were obtained by self-report at the baseline interview.

Risk perception. Perceived risk of having a \( BRCA1/2 \) mutation was evaluated at baseline using one previously validated Likert-style item that asked women to indicate how likely it was that they had a \( BRCA1/2 \) mutation (1 = not at all likely to 4 = definitely). We recoded this item into a dichotomous variable (likely \( v \) not likely) based on the distribution of responses.

Outcomes
Eligibility. Women who had a 5% to 10% prior probability of having a \( BRCA1/2 \) mutation were eligible for study enrollment. Women who did not have a 5% to 10% prior probability were ineligible.

Study enrollment. Women who consented for study enrollment, completed the baseline interview, and accepted the invitation for pretest genetic counseling were categorized as study enrollees. Women who consented for study enrollment, completed the baseline interview, and declined genetic counseling were also categorized as study enrollees if they agreed to participate in follow-up telephone interviews. Women who actively declined study enrollment and those who passively declined enrollment by not responding to multiple attempts to complete the baseline interview were categorized as nonenrollees.

Participation in genetic counseling. Women who completed pretest genetic counseling were categorized as counseling participants. Women who enrolled in the study but declined genetic counseling and those who did not complete counseling after accepting the invitation were categorized as counseling nonparticipants.
Recruiting African American Women

RESULTS

Eligibility for Study Participation
As shown in Figure 1, since initiating recruitment in February 2003 to August 2004, 783 African American women were referred to the study. Most women 492 (63%) were referred from general medical practices (GMPs), 200 (25%) were referred from oncology clinics (ONCs), and 91 (12%) were referred from community oncology resources (COMs). All women referred to the study self-identified as being African American or black.

The referral rate equaled the number of eligible women divided by the total number of women referred to the study. Of the 783 women referred, 164 (21%) were eligible for participation and 619 (79%) were ineligible because their personal or family history of cancer was not suggestive of hereditary disease. Eligible women were most likely to be referred from ONCs (44%) compared with COMs (23%) and GMPs (11%; \( \chi^2 = 96.80; P = .0001 \)). Ineligible women and those who were eligible for participation but pending contact for enrollment were excluded from subsequent analyses; thus, the data presented below evaluate study enrollment among 157 eligible women (95% of the 164 eligible women).

Predictors of Study Enrollment
The enrollment rate equaled the number of women who enrolled onto the study divided by the total number of eligible women. Of 157 eligible women, 98 (62%) enrolled onto the study. As listed in Table 1, family history was associated significantly with enrollment. Women who had two or more affected relatives were most likely to enroll. Study enrollment was also significantly greater among women referred from ONCs and COMs compared with GMPs. There was also a trend for affected women to be more likely to enroll onto the study compared with unaffected women. No other factors were associated significantly with study enrollment.

We used logistic regression analysis to identify factors having independent associations with study enrollment. Because study enrollment was not significantly different among women referred from ONCs and COMs, we combined these groups into one category and evaluated referral site as a two-level variable (ONC/COM v GMP) in the regression model. Referral site was not associated significantly with family history of cancer (\( \chi^2 = 0.74; P = .69 \)) but was related to personal history of disease (\( \chi^2 = 29.83; P = .001 \)); however, this association did not result in multicollinearity (\( r \) for the coefficients = −0.41). Therefore, variables that had a bivariate association of \( P < .20 \) with enrollment (referral site, cancer history, and family history) were included in the regression model.

Only referral site and family history had significant independent associations with study enrollment. Women who had two or more affected relatives were three times more likely to enroll onto the study compared with those who had fewer affected relatives (odds ratio [OR] = 3.18; 95% CI, 1.36 to 7.44; \( P = .01 \)). Compared with women referred from GMPs, those referred from ONCs and COMs were about three times more likely to enroll (OR = 2.97; 95% CI, 1.34 to 6.58; \( P = .01 \)). The effect for cancer history was not significant (OR = 2.00; 95% CI, 0.78 to 5.14; \( P = .15 \)). We reran the logistic regression model excluding women referred from the epidemiologic protocol and the other risk counseling program; the results were unchanged (family history: OR = 3.34, 95% CI, 1.23 to 9.11, \( P = .02 \); referral site: OR = 2.93, 95% CI, 1.24 to 6.90, \( P = .01 \)).

Predictors of Participation in Genetic Counseling
The rate for participation in genetic counseling equaled the number of women who participated in genetic counseling divided by the number of eligible study enrollees. Overall, 48 (50%) of eligible study enrollees (n = 95) participated in genetic counseling (30% of all eligible women [n = 157] contacted for study enrollment). (Three women who enrolled onto the study were undecided about participation in genetic counseling and were excluded from the analysis of genetic counseling participation; therefore, the denominator for this analysis is 95 women.) As listed in Table 2, women with greater education and those at high risk for having a BRCA1/2 mutation were most likely to participate in genetic counseling. Women referred from ONCs were
also most likely to participate in genetic counseling. Affected women were also more likely to participate in genetic counseling compared with unaffected women; however, this effect was not statistically significant ($P = .07$).

No other factors were associated significantly with participation in genetic counseling. To identify factors having independent association with participation in genetic counseling, we used logistic

regression analysis. Because participation in genetic counseling differed among women referred from ONCs, COMs, and GMPs, we used dummy variables to evaluate the effect of referral site; women referred from GMPs were used as the reference group. As listed in Table 3, clinical factors and sociodemographics were not associated significantly with participation in genetic counseling. The addition of referral site improved the overall fit of the model (likelihood ratio test = 14.23; \( P = .001 \)); however, only the effect for the comparison of the ONCs to GMPs was significant. We reran the logistic regression model excluding women referred from the epidemiologic study and the other risk counseling program, and the results were unchanged (OR = 5.09, 95% CI, 1.27 to 20.45, \( P = .02 \) for the comparison of ONCs to GMPs and OR = 2.54, 95% CI, 0.47 to 13.83, \( P = .28 \) for the comparison of COMs to GMPs).

### DISCUSSION

To our knowledge, this is the first empirical study to evaluate the process of recruiting (eg, determination of the proportion of eligible women referred to the study and rates of study enrollment and participation in genetic counseling) African American women to genetic counseling research for BRCA1/2 mutations. Despite receiving a large number of referrals, only 21% of women referred to the study were eligible for enrollment; eligible women were most likely to be identified from oncology resources. This finding is not surprising given the fact that hereditary breast cancer is rare and BRCA1/2 mutations account for only approximately 5% to 10% of all breast cancer occurrences.17-19 Thus, most women in the general population, including those receiving care in oncology settings, are not likely to have a personal and family history cancer that is suggestive of hereditary disease and be eligible for enrollment onto genetic counseling research.

Overall, 62% of eligible women enrolled onto the study and of the eligible enrollees, 50% participated in genetic counseling. Although prior studies have shown that African Americans report concerns about genetics research20,21 and may not participate in genetic registries,4 our enrollment and participation rates are similar to those reported for hereditary breast cancer studies conducted with predominantly white populations.22,23 It is important to note that only half of eligible women participated in genetic counseling. This may indicate that acceptance of genetic testing may be even lower among African American women than previously reported6,24; however, participation in genetic counseling and testing may be greater among women who are specifically seeking these services. Future studies should evaluate reasons for participating and not participating in genetic counseling among African American women.

We found that women who had a stronger family history of cancer were most likely to enroll onto the study. However, family history was not associated with participation in genetic counseling. This suggests that family history may motivate participation in the initial aspects of hereditary breast cancer research, but may not translate into completion of study procedures. Despite this, collecting information on family history from African American women in clinical settings is important to ensure that women with an increased risk for BRCA1/2 mutations are informed about the availability of programs designed to provide education and counseling, and are referred for participation. Participation in genetic counseling may be beneficial to African American women to increase knowledge.

about breast cancer risk factors and to provide information about options for cancer prevention and control. We also found that referral site was associated significantly with study enrollment and participation in genetic counseling. An important consideration, however, is that eligible women were most likely to be identified from ONCs. However, previous studies have shown that African American participation in cancer prevention and control research and treatment trials is limited, even though participants are identified from oncology settings and may have a vested interest in study enrollment to obtain cancer treatment or support services.\(^1\)\(^2\)\(^15\)\(^25\) Our findings suggest that even though recruitment from oncology settings has not translated into high rates of African American participation in most types of cancer research, African American women who are referred from oncology settings may be willing to enroll onto hereditary breast cancer research studies and participate in genetic counseling. It is possible that women referred from oncology settings were most likely to participate in genetic counseling because of increased knowledge about hereditary breast cancer or greater perceived value of genetic risk information.\(^6\) Thus, oncology settings can be an effective resource for identifying African American women who are eligible to participate in hereditary breast cancer research, and referral from these settings may translate into completion of study procedures. Future studies are needed to identify motivations for participating in genetic counseling among women referred from different settings.

In considering the results of this study, some limitations should be noted. First, we were not able to evaluate the effects of sociodemographics on study enrollment. This information was collected after enrollment; however, we did compare participants and nonparticipants in genetic counseling in terms of sociodemographics, and we also compared study enrollees and nonresponders in terms of some baseline variables. An additional limitation is that more than one type of referral personnel was used. Thus, it is possible that women heard about the study through multiple sources or received more detailed information about the study from clinic staff or physicians. However, referral source was not associated significantly with study enrollment; therefore, it is not likely that any potential variation in information received about the study influenced enrollment decisions. However, our study was not powered to detect differences in study enrollment or participation in genetic counseling based on referral from different types of personnel. Thus, experimental studies are needed to compare the effects of different referral sites and sources on African American enrollment in hereditary breast cancer research. Within these designs it will be especially important to evaluate the impact of race of the individual making the referral and completing enrollment procedures on participation decisions.

Despite these limitations, this study highlights the importance of using multiple referral sites to identify African American women at increased risk for hereditary breast cancer. Our findings suggest that African American women at increased risk for having a BRCA1/2 mutation are receptive to enrolling onto genetic counseling research; however, one’s family history of cancer and the referral site may influence decisions about study enrollment and participation in genetic counseling. Increasing awareness about the availability of hereditary breast cancer research among African American women in oncology settings and developing strategies to identify women at increased risk for hereditary disease may enhance African American participation in genetic counseling research. It may also be important to enhance knowledge about hereditary breast cancer and genetic counseling among physicians and clinic staff in GMPs. Although most African American women were referred from general medical practices, fewer eligible women were referred from these sites. Recent studies have shown knowledge about hereditary cancer is limited among primary care providers and most primary care providers believe that they are not qualified to provide genetic services.\(^26\)\(^27\) Educational efforts about hereditary cancer may enhance recognition of women at increased risk for BRCA1/2 mutations in settings where a greater number of African American women may be receiving health care.

**Acknowledgment**

Costs for genetic testing were paid by institutional funds at the Abramson Cancer Center. We thank all of the women who expressed an interest in this study and we are especially appreciative to those who participated in this research.

Low rates of acceptance of BRCA1 and BRCA2 test results among African American women at increased risk for hereditary breast-ovarian cancer

Chanita Hughes Halbert, PhD\(^1\), Lisa Kessler, MS\(^2\), Jill E. Stopfer, MS\(^3\), Susan Domchek, MD\(^4\), and E. Paul Wileyto, PhD\(^2\)

**Purpose:** This study evaluated rates of BRCA1 and BRCA2 (BRCA1/2) test result acceptance among African American women and identified determinants of test result acceptance. **Methods:** Acceptance of BRCA1/2 test results was evaluated among 157 African American women at high and moderate risk for having a BRCA1/2 mutation who were offered genetic testing as part of a clinical genetic counseling research program. **Results:** Twenty-two percent of women received BRCA1/2 test results. Test result acceptance differed between women with ≥10% prior probability of having a BRCA1/2 mutation (34%) and those who had a 5% prior probability (8%). Among women with ≥10% prior probability, test result acceptors were most likely to be married (OR = 5.29, 95% CI = 1.82, 15.38, \(P = 0.002\)) and be less certain about their risk of developing cancer (OR = 3.18, 95% CI = 1.04, 9.80, \(P = 0.04\)). **Conclusion:** These results demonstrate that acceptance of BRCA1/2 test results may be limited among African American women. Being married and having less certainty about one’s cancer risk may motivate acceptance of BRCA1/2 test results among African American women. It may be important to emphasize the possibility that BRCA1/2 test results may not clarify cancer risks during pre-test counseling with African American women to ensure informed decision-making about testing. Genet Med 2006;8(9):576–582.

**Key Words:** African American, BRCA1 and BRCA2, test result, acceptance

Recently, epidemiological studies have shown that the prevalence of BRCA1 and BRCA2 (BRCA1/2) mutations range from 16–28% among African American women who have a personal and family history of breast and/or ovarian cancer suggestive of hereditary disease.\(^1\)–\(^4\) If found to carry a BRCA1/2 mutation, women have an estimated 60–80% lifetime risk of developing breast cancer and a 10–45% lifetime risk of developing ovarian cancer.\(^5\)–\(^7\) Because of the excess rates of breast cancer mortality among African American women,\(^8\),\(^9\) participation in genetic counseling and testing may be beneficial to women at increased risk for hereditary cancer to increase knowledge about cancer risks and options for risk reduction. Efforts are now being made to enhance access to genetic counseling and testing for BRCA1/2 mutations among African American women at increased risk for hereditary disease. Recent research has shown that as many as 50% of African American women may participate in genetic counseling for breast cancer susceptibility,\(^10\) but little is known about rates of acceptance of BRCA1/2 test results or determinants of test result acceptance.

To address this gap in our knowledge, we evaluated rates of BRCA1/2 test result acceptance among African American women at increased risk for hereditary breast and ovarian cancer and identified sociodemographic, clinical, and psychological barriers and facilitators to receiving genetic test results. Because prior studies have shown that cancer-specific worry may influence decisions about participating in genetic counseling among African American women\(^11\) we were interested in exploring the relationship between BRCA1/2 test result acceptance and cancer-specific worry. Other reports have shown that many African American women would want to have genetic testing to be reassured about their cancer risk;\(^12\) however, it is possible that women who are uncertain about their risk of developing cancer may be most likely to receive test results to better define their risk of disease. Thus, we were also interested in determining whether certainty about one’s risk of developing breast cancer is associated with genetic test acceptance. Since previous research has shown that responses to education about hereditary breast cancer and genetic testing may differ among African American women depending on the extent to which information addresses individual concerns,\(^11\) a secondary aim of the study was to explore whether two forms of pre-test counseling, culturally tailored versus standard, influence acceptance of BRCA1/2 test results among women who participate in pre-test counseling. Information on rates and determinants of BRCA1/2 test result acceptance will provide important information on the development of more effective genetic counseling for these high-risk populations.

tion on uptake of this service among African American women at increased risk for hereditary breast and ovarian cancer.

**MATERIALS AND METHODS**

**Study population**

Participants were African American women (N = 157) at increased risk for having a BRCA1/2 mutation. To be eligible for participation, women had to self-identify as being African American or Black and have at least a 5–10% prior probability of having a BRCA1/2 mutation based on their personal and family history of breast and/or ovarian cancer. Prior probability of having a BRCA1/2 mutation was estimated based on the participant’s personal and family history of breast and/or ovarian cancer using risk estimation models and empiric data from prior reports.\(^3,13–15\) The study was approved by the Institutional Review Board at the University of Pennsylvania.

**Procedures**

Women were recruited into the study through a referral network that included seven clinical institutions and community oncology resources located in Philadelphia, PA. At the clinical referral sites, brochures and flyers that contained information about the study were given to all African American women by physicians and clinic staff. Study brochures and flyers were given to women by research staff at community oncology resources. Women interested in learning more about genetic counseling completed a referral form that collected information on race, address, birth date, and personal and family history of cancer. Eligibility was determined by the study genetic counselor following referral and eligible women were mailed an invitation letter that described the study purpose and procedures involved in participation. Some women (N = 27) were referred from a separate epidemiological study that was designed to identify genetic risk factors for breast cancer in African American women and had provided a blood sample before enrolling in this study. However, these women did not receive genetic counseling for hereditary breast-ovarian cancer susceptibility and clinical genetic testing for BRCA1/2 mutations was not performed. Further, referral from the epidemiological study was not associated with decisions about enrolling in this study.\(^10\) Study enrollment included completion of a structured baseline telephone interview that took about 40 minutes to complete. Both study enrollment and the baseline were completed by a trained interviewer at Penn after obtaining verbal consent. Project staff who completed the study enrollment and the baseline telephone interview were African American. The baseline assessed sociodemographics, cancer-specific worry, and risk perception variables. The response rate for the baseline telephone interview and study enrollment was 61% (Fig. 1). At the end of the baseline, women were invited to participate in genetic counseling; those who agreed to participate in counseling were randomized to culturally tailored or standard genetic counseling. Detailed information on these counseling protocols is provided below under “Genetic Counseling Protocols.” Women were recruited into the study from February, 2003 through October, 2005.

**Genetic counseling protocols**

Standard Genetic Counseling (SGC): Following provision of written informed consent, women randomized to SGC received pre-test counseling about hereditary breast and ovarian cancer, the inheritance and prevalence of BRCA1/2 susceptibility genes, the process of genetic testing for BRCA1/2 mutations, and interpretation of genetic test results using a semi-structured protocol. Risk of having a BRCA1/2 mutation was also provided to women along with information about cancer risks associated with BRCA1/2 mutations and the potential benefits, limitations, and risks of genetic testing. Possible test result outcomes (e.g., positive, negative, or variant of unknown significance) were also reviewed. The SGC session lasted about 90 minutes. Similar protocols have been used to provide pre-test counseling in prior studies.\(^16,17\)

Culturally tailored genetic counseling (CTGC): The CTGC protocol provided the same education about hereditary cancer, genetic testing, and risk information as the SGC protocol after written informed consent was obtained. However, consistent with guidelines for providing culturally competent genetic counseling,\(^18,19\) the CTGC protocol included standardized probes to elicit discussion about cultural factors that have been shown to influence decisions about genetic counseling among African American women in prior reports (e.g., spiritual and religious beliefs, communalism).\(^20,21\) For example, women were asked what aspects of their spiritual and religious beliefs influence their decision to have genetic testing to facilitate discussion about the role of these factors in decision-making about genetic testing for BRCA1/2 mutations. Women were also asked questions such as how their familial experiences with breast and ovarian cancer influenced their decisions to have genetic testing to facilitate discussions about values related to communalism. The CTGC sessions lasted 90–120 minutes. The study genetic counselor (LK) took detailed counseling notes after CTGC and SGC to document the issues discussed during pre-test counseling and these notes were reviewed by the PI (CHH) to ensure adherence to the counseling protocols. In addition, counseling sessions were randomly audi-taped and reviewed by the PI to ensure adherence to the counseling protocols. The SGC and CTGC sessions were conducted using a semi-structured protocol that included visual aids to standardize the educational content and a written summary of the educational content was provided to women to refer to after the session. Sessions were conducted individually by a board certified genetic counselor (LK) who was Caucasian.

At the end of culturally tailored or standard genetic counseling, women were given an opportunity to provide a blood sample for genetic testing. Women who were interested in having genetic testing were scheduled for a meeting with a medical oncologist (SD). During this visit, women discussed any new medical issues and were offered a clinical breast examination. Possible test result outcomes, as well as the risks and benefits of genetic testing, were reviewed by the medical oncologist. Spe-
Specific issues that were discussed were the ways that knowledge of BRCA1/2 mutation status might influence medical management (e.g., oophorectomy, enhanced screening) for themselves and their family members, as well as the possibility of variants of unknown significance. Blood samples were obtained from women who were interested in genetic testing following provision of written informed consent at the end of this appointment. When test results became available, women were contacted by telephone by the study genetic counselor to schedule a test results disclosure session. Costs for genetic testing were paid by the participant’s insurance company or by institutional funds at the Abramson Cancer Center. Participants who provided a blood sample were invited to attend an individual test result disclosure and counseling session when their BRCA1/2 test results became available. Following provision of written informed consent, BRCA1/2 test results were disclosed by the genetic counselor and medical oncologist. Women were also provided with information about their risk of developing cancer, individualized guidelines for surveillance and prevention options, and risk of having a BRCA1/2 mutation among family members.

Following disclosure of BRCA1/2 test results and discussion of guidelines for cancer screening and surveillance, a semi-structured culturally tailored protocol was used to facilitate discussion of cultural belief and values that were addressed during the pre-test counseling session among women who were randomized to CTGC. For example, women were asked what aspects of their religious and spiritual beliefs they would use to cope with their BRCA1/2 test results. Women were also asked which family members would they lean on for support following test results disclosure and how would they react if relatives did not want to know their BRCA1/2 test results.

Regardless of test result and randomization to CTGC or SGC, all women received a written report that included an interpretation of their BRCA1/2 test result and guidelines for medical management. In addition, all women were contacted by the study genetic counselor approximately two weeks following the test result disclosure session to answer any additional questions and to provide additional referrals, if needed.

Fig. 1. Flow of Study Procedures. *CTGC, Culturally Tailored Genetic Counseling; SGC, Standard Genetic Counseling. †39 Women who completed pre-test education and counseling provided a blood sample for genetic testing. ‡VUS, Variant of Unknown Significance.
Measures

Sociodemographics
Income, marital status, education, and employment status were obtained during the baseline telephone interview. Responses to these items were re-coded into dichotomous variables (e.g., not married vs. married) based on the distribution of responses.

Clinical factors
Age, personal history of cancer, and family history of disease were obtained by self-report. Women were categorized as being age 50 or younger or older than age 50.

The total number of first-, second-, and third-degree relatives diagnosed with breast and/or ovarian cancer was calculated because it is standard practice to construct a three-generation pedigree for genetic counseling.22 Women were categorized as having two or more affected relatives or less than two relatives affected with breast and/or ovarian cancer.

Psychological variables
Psychological factors were evaluated in terms of certainty about one’s risk of developing cancer, perceived risk of having a BRCA1/2 mutation, and cancer-specific worry. Specifically, we used one Likert-style item validated in previous research on genetic counseling for inherited breast cancer risk to evaluate perceived risk of having a BRCA1/2 mutation.11,23 Certainty about one’s risk of developing cancer was evaluated with a Likert-style item that asked women how certain they were of their chances of getting breast cancer (1 = not at all certain, 2 = a little certain, 3 = somewhat certain, 4 = very certain). Similar types of items have been used in prior research to evaluate certainty about one’s breast cancer risk.24 Responses to these items were re-coded into dichotomous variables based on the distribution of responses (e.g., at risk vs. not at risk and more certain vs. less certain). We used the breast cancer worry scale to evaluate cancer-specific worry.25 This questionnaire asked women to indicate how much they thought about their chances of developing breast cancer and how much thoughts about developing breast cancer impacted their mood and ability to perform their daily activities. This scale has been used to measure cancer-specific worry among women seeking genetic counseling for BRCA1/2 mutations in previous research26 and had good internal consistency in this sample (Cronbach’s alpha = 0.76).

Acceptance of BRCA1/2 test results
Women were classified as either BRCA1/2 test result acceptors or decliners. Acceptors included women who participated in genetic counseling, provided a blood sample for testing, and received BRCA1/2 test results. As in prior reports,16,27 decliners included women who did not receive BRCA1/2 test results within 8–12 weeks of being notified that results were available, women who declined to participate in genetic counseling, and those who declined to provide a blood sample for testing following pre-test counseling. We compared women who declined to participate in genetic counseling to those who declined genetic testing or test results and there were no differences in terms of sociodemographic characteristics (e.g., marital status, \( \chi^2 = 0.19, P = 0.66 \)), clinical factors (e.g., cancer history, \( \chi^2 = 1.28, P = 0.26 \)), or psychological variables (e.g., breast cancer certainty, \( \chi^2 = 0.13, P = 0.72 \)). Costs for genetic testing were paid by institutional funds for women with \( \geq 10\% \) prior probability of having a BRCA1/2 mutation. For women with a 5% prior probability, these costs were paid by insurance companies.

Data analysis
We first generated frequencies to characterize participants in terms of sociodemographics, clinical factors, and acceptance of BRCA1/2 test results. Next, we conducted \( \chi^2 \) analysis to evaluate the relationship between randomization to CTGC and SGC and sociodemographics and clinical factors. We then conducted \( \chi^2 \) tests of association to evaluate the relationship between BRCA1/2 test result acceptance and randomization to CTGC and SCG. We then conducted bivariate analyses to evaluate the relationship between BRCA1/2 test result acceptance and sociodemographics, clinical factors, and cancer-specific worry using a combination of \( \chi^2 \) tests of association for dichotomous variables and non-parametric analysis of variance for continuous measures. These analyses were stratified by BRCA1/2 prior probability because of differences in coverage for genetic testing expenses among women with \( \geq 10\% \) prior probability and those with a 5% prior probability. We then conducted multivariate logistic regression analysis to identify factors having independent associations with BRCA1/2 test result acceptance. Variables that had a bivariate association of \( P < 0.10 \) with test result acceptance were included in the logistic regression model.

RESULTS
Sample characteristics
As shown in Table 1, the sample consisted mostly of women who had \( \geq 10\% \) prior probability of having BRCA1/2 mutation (53%). In addition, most women were ages 50 and younger (61%), not married (69%), had some college education or were college graduates (69%), were employed (62%), and had an annual household income less than $35,000 (52%). Ninety-seven percent of women had health insurance. There were no differences in sociodemographic characteristics between women who had \( \geq 10\% \) prior probability of having a BRCA1/2 mutation and those who had a 5% prior probability. Overall, 64% of women had a personal history of breast and/or ovarian cancer and most women had two or more relatives affected with cancer (59%). In terms of randomization to genetic counseling, 48% of women were randomized to CTGC (N = 65) and 52% were randomized to SGC (N = 71). Women who did not participate in the prior epidemiological study (\( \chi^2 = 6.95, P = 0.01 \)) and those with a high school education or less (\( \chi^2 = 6.22, P = 0.01 \)) were more likely to be randomized to CTGC; however, there were no differences in marital status (\( \chi^2 = 0.13, \)})
Comparison to those who had a 5% prior probability (8%) had however, test result acceptance was greater among women who participated in pre-test counseling. Among participants in pre-test counseling, 47% were test result acceptors and 53% declined. Since there were no differences in test result acceptance among women randomized to CTGC and SGC, we evaluated rates of test result acceptance in the total sample of women who were randomized to CTGC and SGC (N = 157), 22% were test result acceptors and 78% were decliners; 15% were mutation carriers, 65% were carriers of variants of uncertain significance. Since a small number of women with a 5% prior probability received BRCA1/2 test results, only marital status and certainty about breast cancer risk had significant independent associations with test result acceptance. As shown in Table 2, women who were less certain about their risk of developing cancer (42%) were more likely to receive BRCA1/2 test results compared to women who were more certain about their risks (22%) (χ² = 3.51, P = 0.06). No other sociodemographic, clinical factors, or psychological variables were associated significantly with BRCA1/2 test result acceptance.

Acceptance of genetic test results

There were no differences in BRCA1/2 test result acceptance in the total sample of women who were randomized to CTGC and SGC (N = 157) (22 vs. 28%, χ² = 0.80, P = 0.37) or among women who participated in pre-test counseling. Among participants in pre-test counseling, 47% were test result acceptors and 53% declined. Since there were no differences in test result acceptance among women randomized to CTGC or SGC, we evaluated rates of test result acceptance in the total sample of women who enrolled in the study. Among all women (N = 157), 22% were test result acceptors and 78% were decliners; however, test result acceptance was greater among women who had ≥10% prior probability of having a BRCA1/2 mutation (34%) compared to those who had a 5% prior probability (8%) (χ² = 15.14, P = 0.001). Of the women who received test results, 15% were mutation carriers, 65% were BRCA1/2 negative, and 21% had variants of uncertain significance. Since a small number of women with a 5% prior probability received BRCA1/2 test results (N = 6), we did not complete analyses to identify factors associated with test result acceptance among these women; thus, the analysis presented below is based on women with ≥10% prior probability who enrolled in the study (N = 83).

Of the sociodemographic factors, only marital status was associated significantly with BRCA1/2 test result acceptance. Women who were married were significantly more likely to receive BRCA1/2 test results compared to those who were not married (χ² = 9.16, P = 0.002). In addition, cancer-specific worry was greater among women who received BRCA1/2 test results compared to decliners (Kruskal-Wallis χ² = 2.87, P = 0.09). However, women who were less certain about their risk of developing cancer (42%) were more likely to receive BRCA1/2 test results compared to women who were more certain about their risks (22%) (χ² = 3.51, P = 0.06). No other sociodemographic, clinical factors, or psychological variables were associated significantly with BRCA1/2 test result acceptance.

Predictors of test result acceptance

In the multivariate logistic regression model of acceptance of BRCA1/2 test results, only marital status and certainty about breast cancer risk had significant independent associations with test result acceptance. As shown in Table 2, women who were married were about five times more likely than unmarried women to receive BRCA1/2 test results (OR = 5.29, 95% CI = 1.82, 15.38, P = 0.002). In addition, women who were less certain about their cancer risk were about three times more likely to receive BRCA1/2 test results compared to those who were more certain about their risk (42%) were more likely to receive BRCA1/2 test results compared to women who were more certain about their risks (22%) (χ² = 3.51, P = 0.06). No other sociodemographic, clinical factors, or psychological variables were associated significantly with BRCA1/2 test result acceptance.

**DISCUSSION**

Prior reports have evaluated participation in genetic counseling among African American women; however, to our knowledge, this study is the first to document rates of actual BRCA1/2 test result acceptance among African American women at increased risk for hereditary breast and ovarian cancer. Overall, 22% of women received BRCA1/2 test results; once women underwent pre-test counseling, 47% of women received BRCA1/2 test results. These findings suggest that acceptance of BRCA1/2 test results may be limited among African American women at increased risk for hereditary cancer, especially in comparison to acceptance rates reported for other populations. Importantly, however, acceptance rates did not differ between women who received culturally tailored and standard genetic counseling. Cultural beliefs and values are increasingly being recognized as important factors in genetic counseling and our recent study found that African American women who received culturally tailored genetic counseling were more satisfied with some aspects of counseling compared to those who received standard genetic counseling. However, the effect of genetic counseling on BRCA1/2 test result acceptance was based on a limited number of women who completed pre-test counseling; thus, this finding should be interpreted with caution.

The results of this study provide some insight into factors that are likely to motivate acceptance of BRCA1/2 test results among African American women. We found that women who were less certain about their risk of developing breast cancer were about three times more likely to receive BRCA1/2 test results compared to women who were more certain about their risks. Provision of risk information is a key component of genetic counseling for BRCA1/2 mutations and previous research has shown that obtaining information about cancer risks is an important motivation for genetic testing among African American women. However, recent research has shown that many African American women may have BRCA1/2 variants of unknown significance; thus, genetic testing may not clarify cancer risks for these women. This underscores the importance of preparing African American women for this possible outcome during pre-test counseling and ensuring that women understand the clinical implications of genetic test results as part of test results disclosure.

We also found that women who were married were most likely to receive BRCA1/2 test results whereas cancer-specific worry did not have a significant effect on BRCA1/2 test result acceptance. Previous research has demonstrated that guilt about passing a BRCA1/2 mutation to relatives may be a barrier to participation in genetic counseling among African American women. However, women are likely to discuss genetic testing with their partner before making a decision about testing. It is possible that married women may have been encouraged to have testing by their spouses and/or partners (Hughes, unpublished data, 1997). Spouses are an important resource for emotional support following breast cancer diagnosis among African American women; the availability of spousal and/or partner support following test results disclosure may have also motivated women to receive BRCA1/2 test results. Thus, while cancer-specific worry may not be a barrier to BRCA1/2 test result acceptance among African American women, lack of encouragement or support from spouses and/or partners may decrease acceptance of genetic test results.

In considering the results of this study, some limitations should be noted. First, rates of genetic test acceptance were based on 61% of eligible women who enrolled in the study. The challenges associated with recruiting African American women to participate in cancer research are well-documented; however, the enrollment rates for the present study are similar to the rates reported in studies that evaluated genetic testing decisions in Caucasian samples. An additional limitation is that we had limited statistical power to detect small differences in test result acceptance rates between women randomized to CTGC and SGC and the model predicting BRCA1/2 test result acceptance was based on women with ≥10% prior probability of having a mutation. However, to our knowledge, our report includes the largest sample of African American women at increased risk for hereditary breast cancer to be enrolled in a prospective randomized trial and we had 80% power to detect moderate effects in the total sample of women randomized to CTGC and SGC and in the subset of women included in the model predicting test result acceptance. Nonetheless, additional research is needed to evaluate acceptance of BRCA1/2 test results in larger samples of African American women. Since decliners included women who declined genetic counseling as well as those who declined testing or results, additional research may be needed to evaluate testing decisions based on more uniform groups of women who choose not to participate in genetic counseling, decline genetic testing, or elect to not receive results. However, women who declined genetic counseling did not differ from those who declined testing and/or results in terms of sociodemographic characteristics, clinical factors, or psychological variables. Previous research has shown that racial concordance with health care providers may be important for effective communication; the lack of racial concordance between participants and the genetic counselor may explain the low rates of genetic test acceptance observed in this study. However, the majority of African American women were extremely satisfied with genetic counseling even though they were not racially concordant with the counselor. Thus, we do not believe that racial discordance between the counselor and participants was a factor in decisions about genetic testing. However, this is an important area for future research.

Despite these potential limitations, the results of this study demonstrate that acceptance of BRCA1/2 test results may be limited among African American women. Since lack of spousal/partner support may be a barrier to acceptance of BRCA1/2 test results among African American women, it may be useful to identify
other resources for support as women considering testing. Previous research has shown that individuals who have more cohesive relationships with family members are most likely to receive BRCA1/2 test results. Thus, other family members might be able to provide support to women who are not married as these individuals consider genetic testing for BRCA1/2 mutations. Since African American women may be likely to receive BRCA1/2 test results to clarify their risks of developing cancer, our results also underscore the importance of discussing possible testing outcomes and the likelihood that BRCA1/2 test results may not clarify cancer risks as part of pre-test counseling with African American women to ensure that women make informed decisions about testing. Additional research is needed to understand the effects of BRCA1/2 test results, especially uncertain risk information, on psychological functioning and cancer screening behaviors among African American women.

Acknowledgments

This research was supported by Department of Defense grant #DAMD17-00-1-0262. Costs for genetic testing for BRCA1 and BRCA2 mutations were covered in part by institutional funds at the Abramson Cancer Center. We would like to acknowledge Aliya Collier, BA, Kiyona Brewster, MA, ChaChira Smith, and Benita Weathers, MPH, for assistance with data collection and management. We are very appreciative to all of the women who participated in this research.

Abstract

\textbf{Objective:} The objective of this study was to evaluate satisfaction with genetic counseling for \textit{BRCA1} and \textit{BRCA2} (\textit{BRCA1/2}) mutations among African American women.

\textbf{Methods:} Participants were 54 African American women at moderate and high risk for \textit{BRCA1/2} mutations who were offered genetic testing as part of a randomized clinical trial designed to compare the effects of culturally tailored genetic counseling (CTGC) and standard genetic counseling (SGC). Satisfaction with genetic counseling was evaluated using a self-administered questionnaire following culturally tailored or standard pre-test education and counseling.

\textbf{Results:} Overall, the majority of women (96\%) were very satisfied with genetic counseling; however, only 26\% reported that their worries were lessened and 22\% reported that they were able to cope better. Women who received CTGC were significantly more likely than women who received SGC to report that their worries were lessened ($p < 0.05$). In addition, women with household incomes less than US$ 35,000 were significantly more likely to report that the counselor lessened their worries compared to women with higher incomes ($p < 0.05$).

\textbf{Conclusions:} Most African American women were satisfied with genetic counseling; however, women who received culturally tailored genetic counseling were significantly more likely to strongly agree that their worries were lessened compared to women who received standard genetic counseling.

\textbf{Practice implications:} Discussion of cultural beliefs and values during genetic counseling may be beneficial to African American women, especially those with low incomes.

1. Introduction

Recent epidemiological studies have shown that the prevalence of \textit{BRCA1} and \textit{BRCA2} (\textit{BRCA1/2}) mutations ranges between 16\% and 21\% among African American women who have a personal and family history of breast and ovarian cancer that is suggestive of hereditary disease [1–3]. Women found to carry a risk-conferring \textit{BRCA1/2} mutation have an estimated 55–85\% lifetime risk of developing breast cancer and a 15–60\% lifetime risk of developing ovarian cancer [4–6]. Previous research has shown that the majority of African American women who are offered participation in genetic counseling and testing choose to participate [7,8]. However, education and counseling for hereditary breast cancer and genetic testing that is not culturally sensitive may
not be effective for African American women [9]. Hughes et al. [8] found that temporal orientation and religious coping strategies were associated significantly with participating in genetic counseling and testing for BRCA1/2 mutations among African American women. Based on this research, efforts are now underway to increase the effectiveness of genetic counseling programs targeted to African American women by developing protocols that are sensitive to cultural beliefs and values [10]. Despite this, empirical data from randomized clinical trials are not available on satisfaction with culturally sensitive genetic counseling protocols among African American women.

Patient satisfaction is regarded as a valuable indicator of health care service quality, as it reflects the experience of care from the patients’ perspective [11]. With respect to genetic counseling, satisfaction encompasses three dimensions: (1) satisfaction with the professional or technical competence of the health care provider; (2) satisfaction with the counselor’s personal qualities or their affective behavior towards the client; (3) satisfaction with administrative procedures such as the cost of counseling and the convenience of obtaining services [12]. Specific aspects of satisfaction with a genetic counselor’s technical abilities with respect to his or her counseling skills may include the extent to which individuals believe that the genetic counselor explained things clearly, listened to what they had to say, increased their anxiety, or lessened their worries [12]. Satisfaction has been measured in numerous arenas of genetic counseling, ranging from male infertility [13] to pregnant women’s satisfaction with prenatal genetic counseling [14]. Recent studies on satisfaction with genetic counseling for inherited breast–ovarian cancer risk demonstrate that most women are very satisfied with counseling [15–17]. However, African American women are not well represented in these studies. For example, of the 61 women enrolled in the study conducted by DeMarco et al. [15], only 4 were African American women.

We are conducting a prospective randomized clinical trial to compare the effects of culturally tailored genetic counseling (CTCG) and standard genetic counseling (SGC) on decisions about genetic testing, psychological functioning, and health behaviors among African American women at increased risk for hereditary breast–ovarian cancer. Based on prior research showing that standard education and counseling about hereditary breast cancer and genetic testing may not be as effective among African American women relative to white women [9], the CTGC protocol was designed to address cultural factors that have been identified as relevant to health behaviors and clinical genetics among African Americans. For example, Lannin et al. [18] found that religious and spiritual beliefs, such as prayer about cancer can lead to healing, were associated with a greater delay in seeking treatment for breast cancer symptoms. African American women were significantly more likely than Caucasian women to endorse these beliefs [18] and were also more likely to use religious strategies to cope with illness [19]. In other work, high levels of spiritual faith were associated with declining BRCA1/2 test results in a sample composed of mostly Caucasian women [20], however, African American women who worked with God to consider difficult situations were most likely to participate in genetic counseling and testing for BRCA1/2 mutations [8]. Other cultural factors (e.g., temporal orientation, communalism) may also be associated with health behaviors among African American women. For example, African American women who had greater levels of communalism were most likely to decline genetic testing [8]. In addition, African American women with a higher present temporal orientation were significantly more likely to have never had a mammogram compared to women with a lower present temporal orientation [21]. Attention to these factors may facilitate the genetic counseling process among African American women; therefore, the CTGC protocol addressed beliefs and values related to: (1) communalism (e.g., the extent to which familial preferences are more important than individual preferences and one’s primary duty is to the group or family) [22,23]; (2) spiritual and religious beliefs and coping mechanisms (e.g., one’s personal relationship with a higher power and practices and beliefs used to cope with stressful situations) [24,25]; (3) temporal orientation (e.g., one’s cognitive focus in terms of past, present, or future domains that individuals use to understand and give meaning to their life experiences) [26–28]. While increased attention to cultural beliefs and values may enhance the sensitivity of genetic counseling, satisfaction with culturally tailored genetic counseling among African American women has not been evaluated. Therefore, the present study compared satisfaction with CTGC versus SGC among African American women at increased risk for hereditary breast–ovarian cancer. Because previous research has shown that exposure to information about genetic testing for inherited disease risk is limited among African American women [29], we were also interested in determining whether expectations about genetic counseling were met among African American women at increased risk for having a BRCA1/2 mutation. Developing a better understanding of satisfaction with genetic counseling among African American women is needed to develop more effective counseling protocols for this population.

2. Methods

2.1. Study population

This study was conducted at the University of Pennsylvania (Pennsylvania) following approval from the Institutional Review Boards at Pennsylvania and Arcadia University. Participants were African American women at increased risk for having a BRCA1/2 mutation. To be eligible for participation in the study, women had to self-identify as being African American or Black and be at least 18 years of
age. Women also had to have a minimum 5–10% prior probability of having a BRCA1/2 mutation based on their personal and family history of breast and/or ovarian cancer to be eligible for participation in the study because this is considered to be the minimum criteria for clinical genetic testing for inherited breast–ovarian cancer risk [30].

2.2. Procedures

Women were recruited to participate in the study through referrals from physicians and clinic staff at the University of Pennsylvania Health System (UPHS). Women were also recruited through referrals from physicians and clinic staff at community hospitals and health clinics located in Philadelphia, PA, as well as African American breast cancer support groups and other community events (e.g., health fairs). Women who were recruited through physicians and clinic staff at the UPHS and other clinical facilities were told about the study during a clinic visit. At health fairs and breast cancer support groups, written information about the study was given to women following a verbal description of the project. Women could also self-refer to the study by responding to newspaper advertisements. Women who were interested in participating in the study completed a referral form in person or by telephone. It should be noted that eleven women were referred to the study by clinic staff while participating in an epidemiological study that was evaluating genetic risk factors for breast cancer among African American women. However, women in the epidemiological study did not receive genetic counseling for BRCA1/2 mutations or clinical genetic testing for BRCA1/2 mutations; thus, there was no overlap with the present study. Moreover, participation in the epidemiological study was not associated with enrollment in the genetic counseling study [31]. Racial background, date of birth, and personal and family history of breast and ovarian cancer were collected on the referral form. All referral forms were reviewed by the study genetic counselor (LK) to determine eligibility.

Following referral, eligible women were mailed an introductory letter. The introductory letter described the purpose of the study and the procedures involved in participating. A reply card was also included for women to return if they were not interested in being contacted about study participation. Women who did not decline participation were contacted for a baseline telephone interview about 2 weeks after the introductory letter was mailed. The baseline was a structured survey that assessed sociodemographic characteristics, perceived risk of having a BRCA1/2 mutation, and interest in genetic testing. This 40-min interview was administered by a professionally trained interviewer from Penn after obtaining verbal consent. At the end of the baseline, women were invited to participate in a genetic counseling research program for African American women. Women who agreed to participate in genetic counseling were randomized to culturally tailored genetic counseling or standard genetic counseling. Detailed information about the counseling protocols is provided below under “counseling protocols.” Written informed consent was obtained for participation in genetic counseling. At the end of the session, all women were offered genetic testing for BRCA1/2 mutations. All counseling sessions were conducted by a Master’s level, board-certified genetic counselor (LK) who was Caucasian. The study enrollment rate was 62% and of the women who enrolled in the study, 50% participated in genetic counseling [31].

2.3. Counseling protocols

2.3.1. Standard genetic counseling

The standard genetic counseling protocol consisted of education about hereditary breast and ovarian cancer (e.g., BRCA1/2 susceptibility genes), the process of genetic testing for BRCA1/2 mutations, and interpretation of genetic test results. Women randomized to the SGC protocol also received information about cancer risks associated with BRCA1/2 mutations and counseling about their risk of having a BRCA1/2 mutation based on their personal and family history of cancer. Information about the benefits, limitations, and risks of genetic testing were also provided as a part of the SGC protocol. The SGC sessions lasted about 1.5 h.

2.3.2. Culturally tailored genetic counseling

The culturally tailored genetic counseling protocol provided the same basic education about hereditary breast and ovarian cancer, genetic testing for BRCA1/2 mutations, and cancer risk information as the SGC protocol. The CTGC protocol differed from SGC in that it included probes that were designed to facilitate discussion about cultural beliefs and values during the counseling process. Consistent with guidelines for culturally competent genetic counseling [32,33], the CTGC protocol incorporated discussion of beliefs and values related to spirituality and religion, temporal orientation, and communalism. The CTGC protocol focused on these cultural beliefs and values based on previous research showing that communalism, spirituality, and flexible temporal orientation are key aspects of an African American cultural worldview [22,23,28,34,35] and our previous research showing that these beliefs and values are associated with decisions about genetic testing among African American women [8].

Specifically, the CTGC protocol included probes that encouraged women to discuss how their cultural beliefs and values are used to make health care decisions and to cope with medical issues. For example, women randomized to the CTGC protocol were asked “What role does spirituality play in your life and what aspect of your religious and spiritual beliefs would influence your decision to have genetic testing?” to address religious and spiritual beliefs and values. Women were also asked “When you make choices about your healthcare, are you focused on what is going on
now or focused on events that may happen in the future?” to address values related to temporal orientation. The CTGC protocol also included probes that encouraged women to discuss how concerns about family members may influence their decisions about genetic testing and how relatives may be impacted by their testing decisions (communalism). For example, women were asked to describe how their family experiences with breast and/or ovarian cancer influenced their decisions to have genetic counseling, if they talked to any of their family members about participating in genetic counseling, and how they would feel if their family did not want to have genetic testing. Discussion of cultural beliefs and values was facilitated by the inclusion of a genogram during the CGTC protocol. The CTGC sessions lasted about 2 h. Detailed counseling notes that documented the issues discussed during each counseling protocol were completed by the genetic counselor following CTGC and SGC. These notes were reviewed by the PI (CHH) to ensure adherence to the counseling protocols. In addition, counseling sessions were randomly audio taped and reviewed by the PI to ensure adherence to the counseling protocols.

2.4. Measures

2.4.1. Sociodemographic characteristics

Age, household income level, marital status, education level, and employment status were obtained during the baseline telephone interview.

2.4.2. Clinical factors

Personal history of breast and/or ovarian cancer and the number of relatives affected with breast and ovarian cancer were obtained at study referral. Prior probability of having a BRCA1/2 mutation was estimated based on women’s personal and family history of cancer using risk estimation models and mutation prevalence tables [3,30,36,37]. Women were categorized as being at moderate risk (5%) or high (10% or greater) risk for having a BRCA1/2 mutation.

2.4.3. Perceived risk

Perceived risk of having a BRCA1/2 mutation was evaluated at baseline by one Likert-style item that asked women to indicate how likely it was that they had a mutation (1: not at all likely, 2: somewhat likely, 3: very likely, and 4: definitely). This item has been validated in previous research on interest in genetic testing among Caucasian women [38] and has been used in prior research on education and counseling about hereditary breast cancer and genetic testing among African American women [39].

2.4.4. Satisfaction variables

Satisfaction with the genetic counseling was evaluated using Likert-style items. Specifically, women were asked to indicate how satisfied they were with the genetic counseling session (1: not at all satisfied, 2: a little satisfied, 3: moderately satisfied, and 4: very satisfied). In addition, women were also asked to indicate how much they thought the genetic counselor explained things clearly, listened to what they had to say, used language that they could understand, increased their anxiety, lessened their worries, and helped them to cope better (e.g., helped them to deal with information about their cancer risk) (1: strongly disagree, 2: disagree, 3: agree, and 4: strongly agree). Similar types of items have been used to evaluate overall satisfaction with genetic counseling as well as satisfaction with the counselor’s technical ability and affective qualities and the procedural aspects of counseling in previous reports [12,15,16].

We used one Likert-style item to evaluate expectations about genetic counseling. Specifically, women were asked to indicate the extent to which they had exceeded their expectations (1: expectations were exceeded, 2: expectations were met, and 3: expectations were not met). This item has been used in previous research on expectations about genetic counseling [40]. All satisfaction variables were evaluated after the pre-test education and counseling session was completed using a self-administered questionnaire that was given to participants by the genetic counselor.

2.5. Data analysis

Because the sample was small (n = 54), our analyses were primarily descriptive. First, we generated frequencies to characterize the study sample in terms of sociodemographic characteristics, clinical factors, and satisfaction variables. We used Fisher’s Exact Tests (FET) to compare women at high and moderate risk for having a BRCA1/2 mutation in terms of sociodemographic factors and BRCA1/2 perceived risk and to compare women randomized to CTGC and SGC in terms of these variables because of the small sample and cell sizes. We then used FETs to describe the association between counseling group and satisfaction variables. We used this same procedure to describe the association between satisfaction variables and sociodemographic characteristics, clinical factors, BRCA1/2 perceived risk, and counseling group.

3. Results

3.1. Sample characteristics

Participants were 54 African American women at high and moderate risk for having a BRCA1/2 mutation. As shown in Table 1, most women were not married (59%), had some college education or were college graduates (76%), were employed (72%), and had an annual household income of US$ 35,000 or more (52%). In terms of clinical characteristics, 69% of women had a personal history of cancer and most (63%) were at high risk for having a

BRCA1/2 mutation. Fifty percent of women had two or more first-degree relatives affected with breast and/or ovarian cancer. The mean (S.D.) age of participants was 46 (12.2). More than 80% of women were referred to the study by physicians and clinic staff. There were no differences in BRCA1/2 prior probability (p < 0.78), cancer status (p < 0.36), family history of cancer (p < 0.29), marital status (p < 1.00), education level (p < 0.33), employment status (p < 1.00), household income level (p < 0.78), or referral source (p < 0.46) between women randomized to CTGC or SGC. Women at high and moderate risk for having a BRCA1/2 mutation did not differ in terms of marital status (p < 0.09), income (p < 0.40), education (p < 0.33), employment (p < 0.76), or perceived risk of having a BRCA1/2 mutation (p < 0.75).

3.2. Satisfaction with genetic counseling

Overall, women were very satisfied with the genetic counseling. Ninety-six percent of women reported that they were very satisfied with genetic counseling and 4% reported that they were moderately satisfied with counseling. In addition, the majority of women strongly agreed that the genetic counselor listened to what they had to say (87%), explained things to them clearly (83%), and provided them with new information (61%) (see Fig. 1). While more than half of women reported that the genetic counselor cared for them (57%) and understood their concerns (57%), only 26% of women strongly agreed that their worries were lessened and only 22% strongly agreed that they coped better. Despite this, most women indicated that the genetic counselor did not increase their anxiety (57% strongly disagreed) or confusion (80% strongly disagreed).

Because of the low proportion of women who strongly agreed that their worries were lessened or who strongly agreed that they coped better, we selected these items for further analysis to identify factors that were associated with these satisfaction variables. For these analyses, satisfaction variables were re-coded as “strongly agree” versus “else” because we were interested in identifying factors that were associated with the highest level of satisfaction with genetic counseling. As shown in Table 2, women who received CTGC were significantly more likely than women who received SGC to report that their worries were lessened (p < 0.05). In addition, compared to women who had an annual income of more than US$ 35,000, women with lower incomes were significantly more likely to strongly agree that their worries were lessened (p < 0.05). Women with lower incomes and those at moderate risk for having a BRCA1/2 mutation were also more likely than women with higher incomes and those at high risk to strongly agree that they were able to cope better; however, these associations were only marginally significant. Perceived risk of having a BRCA1/2 mutation was not associated significantly with either satisfaction outcome (see Table 2). We did not conduct analyses to determine if overall satisfaction with genetic counseling was associated with sociodemographic characteristics and clinical factors or differed between women who received CTGC and SGC because more than 90% of women reported that they were satisfied with genetic counseling overall.

3.3. Expectations about genetic counseling

Overall, 67% of women reported that their expectations about genetic counseling were exceeded. There were no differences in expectations about genetic counseling between women who received CTGC and SGC. Seventy-one percent of women who received CTGC reported that their expectations were exceeded and 66% of women who received SGC reported that their expectations were exceeded (p < 0.77). Expectations about genetic counseling were not associated with BRCA1/2 prior probability (p < 0.36), cancer history (p < 1.00), family history of cancer (p < 0.44), BRCA1/2 perceived risk (p < 0.73), or sociodemographic characteristics (e.g., marital status, p < 0.77; education level, p < 0.18).
4. Discussion and conclusion

4.1. Discussion

To our knowledge, this is the first empirical study to evaluate satisfaction with genetic counseling for BRCA1/2 mutations among African American women at increased risk for hereditary breast and ovarian cancer. Overall, the majority of women were very satisfied with genetic counseling. These results are consistent with findings reported in prior studies of patient satisfaction with genetic counseling [15,17,41,42] and research on the role of expectancy violations theory in genetic counseling [40]. One possible explanation for the high levels of satisfaction found in this study is that women were not sure what to expect from genetic counseling. Previous research has shown that after adjusting for education level, awareness about genetic testing and knowledge about breast cancer genetics are limited among African American women [29,43,44]. However, more than 60% of women in the present study reported that their expectations about genetic counseling were exceeded. A recent study also found that among African American women who had heard about genetic testing, concern about some of potential limitations and risks of genetic testing are high [43] even though women may have favorable attitudes about the benefits of genetic testing [29,45]. It is possible that women initially had mixed feelings about testing, but their expectations were exceeded following a discussion about hereditary breast cancer and genetic testing and provision of cancer risk information. However, we did not evaluate expectations about genetic counseling prior to the pre-test education and counseling session; thus, future studies are needed to evaluate expectations about genetic counseling among African American women before counseling is provided.

Although expectations about genetic counseling were exceeded for the majority of women and most participants were satisfied with genetic counseling overall, satisfaction with all aspects of counseling was not uniformly high. Only about one-fourth of women strongly agreed that their worries were lessened and that they were able to cope better. It is possible that worries were not lessened because women were provided with new information about cancer risks for themselves and their family members. Interestingly, women who received culturally tailored genetic counseling were significantly more likely than women who received standard genetic counseling to report that their...
worries were lessened. Women who received culturally tailored genetic counseling may have been more satisfied because the CTGC protocol included a discussion of spiritual and religious beliefs and practices that they use to make health care decisions and to cope with medical issues. Discussion of the potential impact of genetic testing on family members during culturally tailored genetic counseling, and how they would cope with these reactions, with the genetic counselor may have also lessened worry among women who received this protocol.

We also found that women with lower incomes were significantly more likely than women with higher incomes to strongly agree that their worries were lessened. Women with low incomes may have fewer resources for health information; it is likely that information about hereditary breast cancer, genetic testing, and risk of having a BRCA1/2 mutation provided by the genetic counselor reduced worries among these women. Another possible explanation is that women with low incomes may have a tendency to give socially desirable responses to questions that evaluate the satisfaction with sources for health information that may not be readily accessible. However, previous research has shown that low income is positively associated with greater distress among African Americans in the general population [46,47] and African American breast cancer survivors [48]. Other work has shown that African American women with low incomes are most likely to experience reductions in psychological distress following a psychoeducational intervention [49]. Our recent study found that African American women at high and moderate risk for having a BRCA1/2 mutation report elevated levels of cancer-specific distress [50]; thus, additional research is needed to evaluate the association between income level and psychological functioning following genetic counseling for inherited breast–ovarian cancer risk among African American women.

In considering the results of this study, several limitations should be noted. First, the small sample size prevented us from conducting multivariate analyses to evaluate the independent effects of sociodemographic characteristics, clinical factors, and counseling group on satisfaction variables. However, the challenges associated with recruiting African Americans to participate in genetic counseling and testing for hereditary cancer have been described in previous reports [51]; to our knowledge, the present report is the first to evaluate satisfaction with genetic counseling among African American women at increased risk for having a BRCA1/2 mutation. It is important to note that the majority of African American women recruited to participate in this study enrolled in the research and completed genetic counseling [31]. Although similar types of items and data collection procedures have been used to evaluate satisfaction with genetic counseling in prior reports [12,15,16], the single items that we used to measure satisfaction and the methods used to collect these data (e.g., self-administered questionnaires distributed by the genetic counselor) may have increased the potential for socially desirable responses. Since we did not evaluate expectations about genetic counseling prior to the counseling sessions, it was not possible to determine how these expectations may have changed. Thus, future studies are needed to evaluate pre- and post-counseling expectations about genetic counseling and satisfaction among larger samples of African American women at increased risk for hereditary breast cancer. Within these studies, it will be important to determine the specific ways in which worry may change following genetic counseling (e.g., worry about one’s cancer risk or worry about one’s family members) and the impact of these changes on health behaviors and communication with family members about genetic testing among African American women. Studies are also needed to evaluate the long-term effects of genetic counseling on psychological functioning among African American women using standardized measures of general and cancer-specific distress and how satisfaction, including changes in worry immediately following genetic counseling, may correspond to post-counseling psychological functioning in this population. Another potential limitation is that while our sample was similar to Philadelphia residents in the 2000 Census in terms of marital status, our study sample may have had greater education and household incomes. However, prior reports have shown that most women who participate in genetic counseling and testing for BRCA1/2 mutations are employed and have some college education [20,52]. Thus, our sample is likely to be similar to women from other racial groups who participate in genetic counseling and testing in terms of sociodemographic characteristics. Another potential limitation is that counseling was provided by one Caucasian genetic counselor. However, the genetic counseling profession is composed primarily of Caucasian women and provision of culturally tailored and standard genetic counseling by a Caucasian genetic counselor is likely to enhance the generalizability of the counseling protocols.

4.2. Conclusions

The results of this study demonstrate that African American women recruited to participate in genetic counseling research are satisfied with counseling for BRCA1/2 mutations. However, satisfaction with some aspects of genetic counseling may vary depending on women’s income level and the type of counseling provided. Women who received culturally tailored genetic counseling were significantly more likely to strongly agree that their worries were lessened compared to women who received standard genetic counseling. The results from this study provide novel, preliminary information on satisfaction with genetic counseling for BRCA1/2 mutations among African American women that have important implications for how genetic counseling for BRCA1/2 mutations is provided to this population.
4.3. Practice implications

Increasingly, efforts are being directed towards enhancing access to genetic counseling and testing for inherited breast–ovarian cancer risk among African American women. Previous research has shown that culturally sensitive educational materials may improve comprehension of complex medical information among ethnic and racial minorities [53–55]. Our results suggest that discussion of cultural beliefs and values during genetic counseling for BRCA1/2 mutations may be effective for African American women, especially those with low incomes. Discussion of cultural beliefs and values related to spiritual and religion, family relationships, and temporal orientation may be one way to facilitate genetic counseling among African American women at increased risk for hereditary breast cancer. Additional research is needed to evaluate the effects of culturally tailored genetic counseling on decisions about genetic testing and psychosocial and behavioral outcomes among this population.

Abstract

Although African American breast cancer survivors are at increased risk for developing breast cancer again, empirical data are not available on breast cancer risk perceptions in these women. This study characterized perceived risk of developing breast cancer in African American breast cancer survivors at risk for having a BRCA1 or BRCA1 (BRCA1/2) mutation and identified factors having significant independent associations with risk perceptions. Participants were 95 African American breast cancer survivors at an increased risk for having a BRCA1/2 mutation. Risk perceptions and sociodemographic, clinical, treatment, and sociocultural factors were collected during a structured telephone interview. Most women reported that they had the same or lower risk of developing breast cancer again compared with other women (53%); however, a substantial minority of women (47%) reported that they had a higher or much higher risk. Factors having significant independent associations with heightened risk perceptions included having a ≥10% prior probability of having a BRCA1/2 mutation [odds ratio (OR), 2.91; 95% confidence interval (95% CI), 1.09-7.72; P = 0.03] and more years of formal education (OR, 2.74; 95% CI, 1.02-7.36; P = 0.05). In addition, women who thought about the past a lot were three times more likely to report heightened risk perceptions compared with those who did not think about the past a lot (OR, 3.72; 95% CI, 1.45-9.37; P = 0.01). These results suggest that it may be important to ensure adequate risk comprehension among African American women as part of genetic counseling for inherited breast-ovarian cancer risk. Discussion of risk perceptions within the context of existing beliefs and values may facilitate this process. (Cancer Epidemiol Biomarkers Prev 2007;16(2):244–8)

Introduction

Each year, thousands of African American women are diagnosed with breast cancer (1, 2). Epidemiologic studies have shown that about 16% to 28% of African American women who have a personal and family history of breast and/or ovarian cancer that is suggestive of hereditary disease carry BRCA1 or BRCA2 (BRCA1/2) mutations (3-5). Although women with a personal history of breast cancer have a 0.56% to 1.0% risk per year of developing a second primary breast cancer, women who carry BRCA1/2 mutations have a substantially higher risk, approaching a 50% lifetime risk (6-9). Breast cancer risk perceptions are important to utilization of genetic testing for BRCA1/2 mutations (10), which may be low among African American women (11). Prior research has shown that African American women without a personal history of breast cancer may not believe that they have an increased risk for developing disease, although known risk factors (e.g., family history of breast cancer in a first-degree relative) are present (12). However, risk perceptions have not been evaluated in African American breast cancer survivors at increased risk for having a BRCA1/2 mutation.

Risk perception is an important construct in the Health Belief Model; according to this model, perceived risk is likely to be influenced by sociodemographic factors, such as education level (13). However, factors associated with breast cancer risk perceptions may also vary within specific ethnic groups (12) and may also be influenced by sociocultural factors, such as temporal orientation. Temporal orientation, or attitudes about specific domains of time (e.g., past, present, and future), is one of the primary contexts through which individuals understand and give meaning to experiences (14). Temporal orientation is an aspect of one’s cultural worldview, which is a set of interrelated beliefs about reality (15-17). Previous research has shown that temporal orientation related to health behaviors may differ among African Americans and Caucasians (18). Because perceived risk of developing cancer implies a specific time trajectory in that these beliefs are an estimate of one’s probability of developing breast cancer again at some point in the future, temporal orientation may also be important to risk perceptions in specific ethnic groups. There is evidence that temporal orientation is an important factor in decisions about breast cancer screening in African American women and participation in genetic counseling and testing for inherited breast cancer risk in Caucasian and African American women (19-21). Previous research has also suggested that temporal orientation may contribute to breast cancer risk perceptions in African American women (12); however, empirical data are not available on the relationship between temporal orientation and risk perceptions in African American breast cancer survivors at increased risk for hereditary disease.

The objective of this study was to characterize breast cancer risk perceptions in African American breast cancer survivors at increased risk for having a BRCA1/2 mutation. Although ethnic group comparisons have been critical to characterizing differences in risk perceptions between African American and Caucasian women (12, 22), a better understanding of within-group variation in risk perceptions is needed to develop more effective genetic counseling and education protocols for African American breast cancer survivors at increased risk.
for having a BRCA1/2 mutation. Therefore, we conducted an exploratory study to describe risk perceptions and identify factors having significant independent associations with perceived risk in African American women with a personal and family history of breast cancer that is suggestive of hereditary disease. Based on prior research (13), we evaluated the relationship between risk perceptions and sociodemographic factors. Because attitudes about time have been shown to influence acceptance of cancer risk information in African American women (19), we also explored the relationship between risk perceptions and temporal orientation. In addition, we evaluated whether risk perceptions varied among women who received a lumpectomy versus mastectomy because type of surgical treatment has implications for ipsilateral breast cancer (23, 24). We also evaluated the relationship between risk perceptions and clinical factors, including family history of cancer and BRCA1/2 prior probability. We predicted that more years of formal education, future temporal orientation, having had a lumpectomy, stronger family history of cancer, and a higher BRCA1/2 prior probability would be associated with heightened risk perceptions.

Materials and Methods

Study Population. This study was conducted at the University of Pennsylvania (Philadelphia, PA) following approval from the Institutional Review Board. Participants were African American women at increased risk for having a BRCA1/2 mutation who were enrolled in a clinical genetic counseling research study. To be eligible for participation, women had to have at least a 5% to 10% prior probability of having a BRCA1/2 mutation based on their personal and family history of breast and/or ovarian cancer. Women who had a 5% to 10% prior probability were eligible to participate in the study because this is considered to be the lower bound for offering clinical genetic testing for BRCA1/2 mutations (25). Because cancer survivorship begins at diagnosis (26, 27), we evaluated age at diagnosis, time since diagnosis, and type of surgical treatment. Specifically, women were categorized as being ≤50 years of age or >50 years of age at diagnosis because this is one criterion used to determine if one’s personal history of cancer is suggestive of hereditary disease. In addition, women were asked to provide the month and year in which they were diagnosed with breast cancer. We recoded time since diagnosis as <1 year, 1 to 5 years, or >5 years. Women also provided information on the type of surgical treatment received (mastectomy or lumpectomy).

Temporal Orientation. We used three questions from the Temporal Orientation Scale (30) to evaluate past, present, and future temporal orientation. This instrument has been validated extensively in previous research with African Americans and Caucasians (30). Because our prior research showed that this instrument has good internal consistency among African American breast cancer survivors at increased risk for hereditary disease (19), we selected one item that had a high factor loading with its respective subscale in prior research; or had acceptable face validity to minimize respondent burden. These items were as follows: “I think about the past a lot” (past temporal orientation, factor loading = 0.84); “I try to do things that help me get what I want in the future” (future temporal orientation); and “If I take care of the present, the future will take care of itself” (present temporal orientation, factor loading = 0.50). Women were asked to indicate if they agreed or disagreed with each item (1 = strongly disagree; 2 = disagree; 3 = neutral; 4 = agree; 5 = strongly agree). We recoded these items into dichotomous variables (strongly agree/agree versus strongly disagree/disagree/neutral) for analysis because responses to these questions were skewed.

Breast Cancer Perceived Risk. We used one Likert-style item to evaluate breast cancer risk perceptions. Specifically, women were asked what their chances of getting breast cancer again were compared with other women their age (1 = much lower; 3 = neutral; 4 = agree; 5 = strongly agree). We recoded these items into dichotomous variables (strongly agree/agree versus strongly disagree/disagree/neutral) for analysis because responses to these questions were skewed.
2 = a little lower; 3 = about the same; 4 = a little higher; 5 = much higher). This item has been validated in prior reports (31) and has been used to measure breast cancer risk perceptions in African American women (12).

**Data Analysis.** First, we generated descriptive statistics to characterize the study sample in terms of sociodemographics, clinical factors, temporal orientation, and perceived risk. We then conducted bivariate analyses using \( \chi^2 \) tests of association to evaluate the relationship between risk perceptions and sociodemographics, clinical factors, and temporal orientation. As in previous research (12), we recoded breast cancer risk perceptions into a dichotomous variable (much/little lower/same risk versus much/little higher risk) to facilitate interpretation of the bivariate analyses. Next, we used logistic regression analyses to identify factors having independent associations with perceived risk of developing breast cancer. Because the sample size was limited, we used a conservative criterion to select variables for inclusion to avoid overfitting the model; variables that had a bivariate association of \( P < 0.10 \) with perceived risk were included in the logistic regression model.

**Results**

As shown in Table 1, most participants were not married, had some college education or were college graduates, and had incomes >$35,000. Most women also had a \( \geq 10\% \) prior probability of having a BRCA1/2 mutation. The mean age of participants was 49 (SD, 10.9). In terms of experiences with breast cancer, most women were <50 years of age when they were diagnosed, had a lumpectomy, and were diagnosed about the past a lot were about four times more likely than women who had more years of formal education and those who thought about the past a lot. Women who had a \( \geq 10\% \) prior probability of having a BRCA1/2 mutation were also likely to report that they had a high risk of developing breast cancer again compared with women with less education and those who did not think about the past a lot. Women who had a \( \geq 10\% \) prior probability of having a BRCA1/2 mutation were also likely to report that they had a high risk of developing breast cancer.

NOTE: Age was evaluated as a continuous variable [age: low/same risk (mean, 50.2; SD, 12.3) versus high risk (mean, 46.9; SD, 9.0); \( t = 1.50; P = 0.14 \)].

**Discussion**

To our knowledge, this is the first empirical study to evaluate perceived risk of developing breast cancer again in African American breast cancer survivors at increased risk for having a...
BRC1/2 mutation. Although the majority of women reported that they had the same or lower risk of developing breast cancer again, it is important to note that almost half of women reported that they had a higher or much higher risk. Previous research has shown that objective risk factors for developing breast cancer may not be correlated with women’s perceived risk of disease (32); heightened breast cancer risk perceptions were only attributed to subjective experiences with disease among unaffected African American women (12). Although risk factors, such as family history of cancer, were not associated with risk perceptions in the present study, women who had a ≥10% prior probability of having a BRC1/2 mutation were most likely to report that they had a high risk of developing breast cancer again. We also found that more years of formal education were associated significantly with heightened risk perceptions. It could be that more years of formal education increases exposure to cancer-related information (33, 34). Another possible explanation is that women with more years of formal education may be better able to comprehend complex information about breast cancer risk, especially the ways in which their personal and family history of disease contribute to their chances of developing breast cancer. Similarly, women with a higher BRC1/2 prior probability may recognize aspects of their personal and family history of disease that increase their risk of disease. Although women reported positive attitudes related to future and present temporal orientation, only women who thought about the past a lot were most likely to report that they had a high risk of developing breast cancer again. Past temporal orientation is characterized by thinking about past experiences; memories of past events are important to how individuals think, feel, and behave (35, 36). Individuals who think about the past a lot may also have a tendency to relive past events, especially those that are highly emotional (36).

Previous research has shown that experiences with breast cancer may remain salient to African American women several years after diagnosis and treatment (37, 38). It is possible that women who think about the past a lot focus on and continue to think about their personal and family experiences with breast cancer diagnosis and treatment. Because past experiences with disease may still be salient to women who think about the past a lot, these women may be likely to believe that they have a high risk of developing breast cancer again. Thus, risk perceptions may be based on a continued sense of vulnerability among African American breast cancer survivors who think about the past a lot. However, our measure of temporal orientation was not specific to breast cancer experiences. Future studies are needed to evaluate the extent to which breast cancer survivors think about specific experiences with diagnosis and treatment.

In considering the results of this study, some limitations should be noted. First, the sample was limited to 95 African American breast cancer survivors who were interested in genetic counseling. Several studies have described the difficulties recruiting African American women to participate in cancer research (39, 40), including studies on hereditary breast cancer research (41, 42). Despite these challenges, our enrollment rates (62%) are similar to the rates observed for participation in hereditary breast cancer research among Caucasian samples (43, 44). The cross-sectional nature of the study is an additional limitation that underscores the importance of prospective studies to evaluate changes in breast cancer risk perceptions in African American breast cancer survivors at increased risk for hereditary disease following genetic counseling and testing for BRC1/2 mutations. An additional limitation may be that we only evaluated comparative risk perception within the context of age using one Likert-style item. This approach may not reflect all of the ways in which subjective experiences with the risk of developing breast cancer (e.g., compared with women from other races and with women without a personal history of cancer) and does not provide an assessment of women’s absolute perceived risk. However, definitive data on the best methods for evaluating risk perception are not yet available (45) and a recent study showed that there is a high degree of correlation among different types of risk perception measures (e.g., comparative, numerical, and verbal risk perception measures; ref. 46). Moreover, prior research has shown that the item we used predicts acceptance of BRC1/2 test results (10) and is sensitive to changes in risk perception after genetic counseling and receipt of BRC1/2 test results among individuals at increased risk (47). Nonetheless, additional research is needed to determine the most effective ways of evaluating risk perceptions (e.g., comparative measures based on age, race, and cancer history or absolute measures) among African American women. Another possible limitation is that data on clinical factors (e.g., family history of cancer and cancer treatment) were collected by self-report, which may be subject to recall bias. However, recent studies have shown that information on family history and breast cancer treatment may be accurate in women diagnosed with breast cancer (48, 49). It is also important to evaluate whether perceived risk of developing breast cancer again is associated with receipt of adjuvant therapy and prognostic indicators, such as stage of disease, nodal status, and tumor size. Because we did not evaluate ethnic group differences in breast cancer risk perceptions, future studies are also needed to determine if risk perceptions differ among African American and Caucasian breast cancer survivors at increased risk for having a BRC1/2 mutation.

Despite these potential limitations, the results of the present study show that the majority of African American breast cancer survivors at increased risk for hereditary breast cancer do not believe that they have an increased risk for developing breast cancer again. Provision of information about risks of having a BRC1/2 mutation and the likelihood of developing cancer are integral aspects of genetic counseling for inherited breast cancer susceptibility (50). Our findings suggest that it may be important to place greater emphasis on provision of cancer risk information during genetic counseling with African American breast cancer survivors. As part of these efforts, it may be especially important to ensure adequate risk comprehension among women with lower levels of formal education. This could be achieved by discussing the basis of risk perceptions during genetic counseling with African American breast cancer survivors to identify factors and experiences that contribute to these beliefs. This may identify knowledge deficits that need to be addressed as well as specific experiences that are salient to women’s beliefs about their chances of developing breast cancer again. Because risk perceptions may also be important to decisions about genetic testing for BRC1/2 mutations (10), exploration of the basis of risk perceptions may also facilitate testing decisions by putting this choice into the context of existing beliefs and motivations for testing.

Short Report

Psychological functioning in African American women at an increased risk of hereditary breast and ovarian cancer

Despite attention to psychological issues during genetic counselling and testing for hereditary breast and ovarian cancer risk, limited information is available on cancer-specific distress among African American women being targeted for participation in counselling and testing. Therefore, the purpose of this study is to examine cancer-specific distress in African American women at an increased risk of hereditary breast and ovarian cancer and to identify factors having significant associations with distress in this population. Respondents were 141 African American women identified for participation in genetic counselling and testing for BRCA1/2 mutations. Overall, respondents reported moderate levels of cancer-specific distress. Younger age (coefficient = 6.0, p = 0.001), being unemployed (coefficient = −5.0, p = 0.01), and having a personal history of cancer (coefficient = 5.0, p = 0.02) had significant associations with intrusion. Younger age was also associated significantly with greater avoidance (r = 6.0, p = 0.02). These results suggest that African American women aged 50 and younger, those who are unemployed and women with a personal history of breast or ovarian cancer may be the most vulnerable to experiencing elevated levels of distress during genetic counselling and testing. Greater attention to psychological issues, including concerns about cancer and cancer risks, may be needed during genetic counselling and testing for BRCA1/2 mutations with these women.

Based on studies, showing that the prevalence of risk-conferring BRCA1 and BRCA2 (BRCA1/2) mutations ranges between 16 and 21% in African Americans (1, 2), African American women are being targeted for participation in genetic counselling and testing. Attention to psychological issues is an important aspect of genetic counselling and testing (3); it is recommended that psychological support be provided to individuals considering testing and those receiving results (4, 5). Previous research has showed that African American women are vulnerable to experiencing cancer-specific distress (6, 7); however, few studies have identified factors that contribute to this vulnerability. One study found that sociodemographics were most important to psychological functioning in African American and Caucasian women (8). However, for a number of historical and social reasons, African Americans and Caucasians differ on sociodemographics (8, 9). Thus, confounding with ethnicity makes it difficult to understand the effects of sociodemographics on psychological functioning in studies that compare African American and Caucasian women. Within-group comparisons are needed to identify factors that are associated with psychological functioning in African American women being targeted for participation in genetic counselling and testing for BRCA1/2 mutations.

This study evaluates cancer-specific distress in African American women at an increased risk of hereditary cancer and identifies factors...
assisted significantly with distress. Based on prior research showing that sociodemographics influence psychological functioning (8), we hypothesized that having fewer socioeconomic resources would be associated with greater distress. We also predicted that distress would be greater among women affected with cancer because of more direct experiences with the disease. We also hypothesized that BRCA1/2 risk perception would contribute to distress. A substantial amount of complex information needs to be covered during pretest education and test result disclosure (10); identifying African American women in greatest need for psychological support may facilitate the process of providing genetic counselling.

Materials and methods

Participants

Respondents were 141 African American women at an increased risk of having a BRCA1/2 mutation who were recruited from the University of Pennsylvania (Penn) and the Georgetown University Medical Center (GUMC). Women had to self-identify as being Black or African American and have a 5–10% prior probability of having a BRCA1/2 mutation to be eligible for participation (11, 12). The IRB at both centres approved the research. It should be noted that some women at Penn (n = 22) provided a blood sample as part of a separate study to understand genetic risk factors for breast cancer before being contacted for the present study. However, clinical genetic testing for BRCA1/2 mutations was not performed and none of these women received genetic counselling. Study site was controlled for in the statistical analysis.

Procedures

Respondents were recruited into the study using similar procedures at both centres. Specifically, women were given written information about the study by a physician or clinic staff during an office visit or community event. Women who were interested in learning more about the study were asked to complete a referral form that included their racial background, contact information, date of birth and personal and family history of breast and/or ovarian cancer. At GUMC, women were identified from mammography and oncology clinics; at Penn, women were identified from the University of Pennsylvania Health System (UPHS), other health care facilities and community resources. Genetic counsellors at both sites reviewed referral forms to determine eligibility.

Following referral, eligible women were contacted to complete a baseline telephone interview. The response rate to the baseline was 62% at GUMC and 65% at Penn. As the majority of women were recruited at Penn, we compared these women who completed the baseline to decliners in terms of clinical factors. Women at moderate risk (χ² = 4.04, p = 0.04) and those with fewer relatives affected with cancer (χ² = 8.33, p = 0.004) were significantly the most likely to decline the baseline. Cancer history and age were not associated significantly with declining the baseline. The baseline was a structured 40-min interview that measured sociodemographics, BRCA1/2 risk perception and cancer-specific distress. Identical questions were used to evaluate these variables in the surveys completed at Penn and GUMC. At the end of the survey, women were invited to participate in genetic counselling. This report focuses on data collected during the baseline before genetic counselling.

Measures

Predictor variables

Study site. The site from which women were recruited was obtained from research records.

Sociodemographics. Likert-style items were used to obtain marital status, income, education and employment status. We re-coded these items into dichotomous variables based on the distribution of responses. Respondents were categorized as being ≤50 or >50, because this was the criteria used for determining whether one’s family history of cancer was suggestive of hereditary disease.

Clinical factors. Personal history of breast and/or ovarian cancer and the number of relatives affected with these diseases were obtained. Because the total number of affected relatives is used to determine whether someone’s family history is suggestive of hereditary cancer (12), family history was calculated as the total number of affected relatives. Family history was re-coded into a dichotomous variable (≥2 vs <2 relatives) based on the frequency of responses. Probability of having a BRCA1/2 mutation was estimated based on the respondent’s personal and family history of cancer using prior probability models and mutation prevalence tables (12–14). Respondents
were categorized as being at moderate (5%) or high (>10%) risk of having a BRCA1/2 mutation.

**Perceived risk.** Perceived risk was evaluated using a Likert-style item that asked respondents how likely it was that they had a BRCA1/2 mutation. This item has been used in previous research on psychological functioning in African American and Caucasian women seeking education and counselling about hereditary breast and ovarian cancer (5).

**Outcome variable**

**Cancer-specific distress.** We used the Impact of Event Scale (IES) (15) to evaluate cancer-specific distress. The IES is a 15-item Likert-style instrument that measures the frequency of intrusive thoughts about cancer and attempts to avoid cancer-related thoughts and feelings. The IES has been used in previous studies on psychological functioning in African American women (6, 9, 16). The avoidance and intrusion scales had excellent internal consistency (Cronbach’s alpha = 0.85 and 0.86, respectively).

**Data analysis**

We first generated descriptive statistics to characterize respondents in terms of sociodemographics, clinical variables and cancer-specific distress. Then, we performed bivariate analyses to evaluate differences in predictor variables and distress between women recruited at Penn and GUMC. Because distress scores were not normally distributed, we used non-parametric analysis of variance, using the Kruskal–Wallis test, to evaluate the association between distress and predictor variables. We used multivariate median regression analysis (17) to identify predictors of cancer-specific distress while controlling for study site and variables associated significantly with completing the baseline. Predictor variables that had a significant association of p < 0.10 with distress were included in the regression models.

**Results**

**Sample characteristics**

Table 1 shows the characteristics of respondents. All women referred to the study self-identified as being African American or Black. There were no differences in sociodemographics, perceived risk or distress between respondents recruited at Penn and GUMC; however, a greater number of women at a high risk of having a BRCA1/2 mutation ($\chi^2 = 5.65, p = 0.02$) and women with a personal history of cancer ($\chi^2 = 6.06, p = 0.01$) were recruited at GUMC. There were no differences in family history between respondents recruited at Penn and GUMC ($\chi^2 = 0.26, p = 0.61$).

**Descriptive information on cancer distress**

According to clinical criteria for cancer-specific distress (18, 19), respondents reported moderate levels of distress. The mean (SD) score for the total IES was 17.56 (16.75). The mean (SD)

scores for intrusion and avoidance were 8.28 (8.30) and 9.29 (9.38), respectively. The median score for both intrusion and avoidance was 6.0.

Association between cancer distress and sociodemographics, clinical factors and perceived risk

As showed in Table 2, younger age was associated significantly with greater avoidance and intrusion. However, being unemployed was only associated significantly with greater intrusion. Of the clinical factors, cancer history was associated significantly with intrusion and was marginally associated with avoidance. Higher probability of having a BRCA1/2 mutation was associated significantly with greater avoidance, whereas BRCA1/2 risk perception was associated significantly with intrusion. Income, marital status, education and family history were not associated significantly with avoidance or intrusion.

Multivariate regression model of cancer distress

As showed in Table 3, only age had a significant effect on avoidance; avoidance was greatest among women ≤50. Cancer history, employment status and BRCA1/2-perceived risk had significant effects on intrusion. Women affected with cancer, those who were not employed and women who believed that they were at the risk of having a BRCA1/2 mutation reported greater intrusion, compared to unaffected women, those who were employed and women who did not believe that they were at the risk of having a BRCA1/2 mutation.

Discussion

To our knowledge, this is the first empiric study to evaluate cancer-specific distress in African American women at an increased risk through having a BRCA1/2 mutation. Similar to Caucasian women undergoing genetic counseling (20), African American women reported moderate levels of distress. Although previous research has shown that income, marital status and education contribute to psychological functioning in African American women (8), these factors were not associated with distress in the present study. However, women ≤50 were significantly most likely to report greater avoidance and intrusion. Younger age has been associated with cancer-specific distress in African American women in other studies (16, 21). In families at the risk of hereditary breast–ovarian cancer, these diseases occur with an early age of onset and BRCA1/2 mutation carriers have an increased risk of developing breast and ovarian cancer (22–25). It is possible that distress was greater in younger women because of more frequent thoughts about their cancer risk and greater attempts to avoid thinking about their risk of disease.

Consistent with other reports (21, 26), BRCA1/2 risk perception was associated significantly with distress. However, risk perception only had a significant effect on intrusion. Similarly, cancer status was only associated significantly with intrusion. Women with a personal history of cancer and who have a BRCA1/2 mutation have an increased risk of developing contralateral disease (24, 27–29). It is possible that intrusion was higher among affected women because of more frequent thoughts about the possibility of cancer recurrence. We also found that unemployed women reported greater intrusion than employed women. It is possible that unemployed women were more distressed because of worry about the ability to pay for cancer screening tests needed to manage their cancer risk. However, studies are needed to evaluate perceived risk of developing contralateral disease (24, 27–29). It is possible that intrusion was higher among affected women because of more frequent thoughts about the possibility of cancer recurrence. We also found that unemployed women reported greater intrusion than employed women. It is possible that unemployed women were more distressed because of worry about the ability to pay for cancer screening tests needed to manage their cancer risk. However, studies are needed to evaluate perceived risk of developing cancer again and the impact of diagnosis and treatment on intrusion in African American breast cancer survivors at an increased risk of hereditary disease. Studies are also needed to identify factors that are associated with risk management behaviours in African American women at an increased risk of hereditary cancer. It will be especially important to identify barriers to cancer screening in this population.

In considering the results of the present study, some limitations should be noted. First, approximately 60% of women completed the baseline telephone interview. However, our participation rates are similar to those reported in other cancer research with African American women (8, 30). Our results may have limited generalizability, because women at moderate risk and those with fewer affected relatives were most likely to decline completing the baseline. The cross-sectional nature of the data is another limitation; longitudinal studies are needed in order to evaluate changes in cancer-specific distress in African American women.

Despite these potential limitations, the results of this study have important implications for genetic counselling targeted to African American women. Prior studies have showed that psychological functioning may influence the comprehension of genetic risk information (31) and testing decisions (9, 32). Our results shed light on African American women who might have the greatest need for psychological support during counselling. More extensive discussion of reactions to different testing scenarios and concerns about the familial impact of genetic testing as well as identification of culturally sensitive coping strategies and sources for emotional support (e.g. religion and spirituality) may increase the cultural sensitivity of genetic counselling for African American women. Exploration of past experiences with cancer, including the experiences of other family members, may be another strategy for providing culturally tailored genetic counselling to these women (33).

As African American women are targeted for participation in genetic counselling and testing, it will be important to design protocols that are sensitive to their psychological needs.
