This report documents an internally developed Python class that takes in a set of data files and organizes them into effective data structures that are suitable for the subsequent extraction, processing, and analysis. The report includes usage examples by describing Python snippets that perform statistical calculations and that transform the data into comma-separated values. Sample input and output data are appended to the report.

Distribution List 24
1. Introduction

The U.S. Army Research Laboratory (ARL) has been developing intrusion detection systems (IDS) intended for tactical wireless mobile ad-hoc network (MANET) systems through various research programs, e.g., the Collaborative Technology Alliance (CTA) and Science and Technology Objective (STO) programs. ARL also empirically evaluates newly developed and experimental IDS in its wireless emulation laboratory (WEL).

In a recent evaluation, ARL captured a set of data describing quantitative network utilization and performance and saved them in a record file for each run. (The description and an example of a record file are presented respectively in subsequent paragraphs and in appendix A.) To parse these record files, ARL had a computer program\(^1\) implemented as a Python\(^2\) script containing two main functions: parseAllFiles and separateTestsByKeys. The former was to read, parse, and return the data stored in a list of dictionaries, and the latter was to take the returned dictionary to create another dictionary whose keys are the concatenation of three types of data: (1) attack type, (2) node density, and (3) detector type. The functional behavior of the former appeared to perform as expected, but that of the latter was still to be tested and evaluated for correctness and usability.

As a script, the computer program was written in a procedural-programming style providing a specific functionality, solving an exact problem at a certain time. The script thus was designed to run as an independent Python application, not as a module that could be imported in a Python shell for an interactive session or incorporated into another module. Therefore, as an alternative to the script, a new Python class was designed and implemented, and it is called the ParseIDSdata class.

This report documents the ParseIDSdata class that also takes in a set of record files and organizes them into a list of dictionaries as the current script does. That is the only common functionality between the current script and the new class. The ParseIDSdata class additionally provides the user a set of data services, implemented as callable methods, for retrieving specific types of data in the input files. The retrieved data are then used for subsequent analysis and processing. As the term “class” implies, it is built using object-oriented (OO) techniques that offer the benefits of reusability, extensibility, and maintainability. In addition, because the class was implemented using Python, the user can import the class into a Python shell for an interactive session with the class, experimenting with its features or developing new applications.

The intended readers of this report include technical personnel who are interested in using the ParseIDSdata class to inspect, extract, or process record files. The report includes three usage

\(^1\)The functions were created by Cem Karan of ARL in 2007.
examples of the ParseIDSdata class. The first example presents a screenshot of an interactive session. The second example provides an implemented method that extracts a specific set of data and calculates its statistics. The last example illustrates a way to transform a set of data into comma-separated values. The internal structures, operations, and interfaces of the examples are explained in this report.

The rest of this report consists of four sections. The next section describes the structure of a record file. Section 3 presents and explains the functional behavior and the outputs of the ParseIDSdata class. Section 4 gives usage examples of the ParseIDSdata class. Section 5 concludes the report.

2. The Record File

Each record file consists of two sections: (1) a metadata section and (2) a data section. The metadata section describes the informational contents in the file. The data section has one or more named blocks of data. Each block consists of data lines. Each data line is a name-value pair (e.g., minRxHsls = 96). Non-data lines, such as comments and blank lines, are also included in the file to improve readability and intelligibility. An input line is a comment line if its first visible character is the percent (%) character. The structure of the file is depicted below:

```
Metadata { Data Block 1 } { Data Block 2 } ... { Data Block N }
```

2.1 Metadata

The metadata section has at most five name-value pairs to provide information about the following data blocks. The five names include NODE_DENSITY, DATE & TIME, Attack Type, Attacker Node, and DETECTOR. The first four names always appear in the sample set of data, but the last one, the DETECTOR name, does not consistently appear.

```
DATE & TIME= 08-22-07_14:40
NODE_DENSITY= low_dense
Attacker Node= node47
Attack Type= FAST HELLO
DETECTOR= SPEC
```

The value of the DATE & TIME field is unique in every data file, and it matches the name suffix of an input file, e.g., record_08-22-07_14:40. (On Microsoft Windows, the ‘.’ character cannot be used to name a file. Therefore, it is converted into the ‘_’ character.) The values of other
fields are not unique. For example, the value of the NODE_DENSITY field of many input data files have the same value, e.g., low_dense.

2.2 Data Blocks

Each data block is enclosed between a pair of curly brackets “{}”. The open-curly bracket ‘{’ signifies the start of a data block, and the close-curly bracket ‘}’ signifies the end. The brackets themselves are not part of the data. Each data block has a set of keywords describing its own contents. The “Name” key word is a special one because it is the name of the associated block. Below is a short example of a data block:

```
{  
    Name = PreBANDWIDTH COMSUMPTION  
    %All Bandwidth Consumption Calculations are in bps
    AllReceivedTraffic = 434.41
    ...
    TransmittedPmsTraffic = 245.80
} 

{  
    Name = BANDWIDTH COMSUMPTION  
    %All Bandwidth Consumption Calculations are in bps
    AllReceivedTraffic = 1.3857e+05
    ...
    minTxPms = 482.40
} 

{  
    Name = CALCULATIONS LATENCY  
    Attack-Jmap = 31
    ...
    False Detection = 0
}
```

3. The ParseIDSdata Class

The ParseIDSdata class is designed to read in the contents of record files and organize them in data structures for subsequent extraction and processing. Invoking the class requires (1) the specification of the directory in which the data files reside (e.g., records) and (2) the common name prefix of all the data files (e.g., report_). The following statement instantiates an object of type ParseIDSdata:

```python
o = ParseIDSdata(datdir="records", prefix="report_")
```
3.1 Interfacing Methods

The class provides several methods for retrieving and printing a set of specific data. The data retrievers always return to their caller an object referring to the requested data. The data printers format and print the requested data to the screen. The names of the methods are listed and explained below.

<table>
<thead>
<tr>
<th>Data Retriever</th>
<th>Data Printer</th>
</tr>
</thead>
<tbody>
<tr>
<td>get_metadata_list()</td>
<td>print_metadata()</td>
</tr>
<tr>
<td>get_name_set()</td>
<td>print_name_set()</td>
</tr>
<tr>
<td>get_idsinfo()</td>
<td>print_idsinfo()</td>
</tr>
<tr>
<td>get_attack_types()</td>
<td>print_attack_types()</td>
</tr>
<tr>
<td>get_datalist()</td>
<td></td>
</tr>
<tr>
<td>extract_data()</td>
<td></td>
</tr>
</tbody>
</table>

- The `get_metadata_list` method returns a list of dictionaries. The length of the list tells the number of input data files because each file has a metadata section. Each dictionary stores the metadata of each file. The `print_metadata` method prints the metadata of each input file to the screen as shown below:

```
NODE_DENSITY = low_dense
DATE & TIME = 08-17-07_14:20
Attacker Node = node41
Attack Type = DROP VALID NEIGHBOR
...
...  
NODE_DENSITY = low_dense
DATE & TIME = 08-17-07_14:08
Attacker Node = node27
Attack Type = DROP VALID NEIGHBOR
```

- The `get_name_set` method returns the names of all the data blocks in a set of strings. The size of the set indicates the number of distinct categories of input data. Each string is the name of a data block or that of the metadata section. The `print_name_set` method prints the names to the screen. The example below shows four different categories of data:

```
Block Name: BANDWIDTH COMSUMPTION
Block Name: CALCULATIONS LATENCY
Block Name: PreBANDWIDTH COMSUMPTION
Block Name: Metadata
```
• The get_idsinfo method returns the information about all the input data in a dictionary. The keys of the dictionary are derived from the name-value pairs found in the metadata section of all the input files. The value of each key is a set of a particular type of data, which can be inspected by printing them on the screen using the print_idsinfo method. The output of the print_idsinfo method reveals information about the input data. For example, two types of detectors (SPEC and SPARTA) were found in the input data as shown below:

```
NODE DENSITY  : set(['low_dense','medium_dense','high_dense'])
DATE & TIME : set(['08-17-07_14:20', ..., '08-21-07_14:32'])
DETECTOR : set(['SPEC', 'SPARTA'])
Attacker Node : set(['node27', ..., 'node41'])
Attack Type : set(['FAST HELLO','DROP VALID NEIGHBOR'])
```

The length of each set tells the number of distinct categories in the set. The length of the NODE_DENSITY set indicates the number of node densities. The length of the DATE & TIME set shows the number of data files because every file has this information. The length of the Attacker Node set reveals the number of nodes that act as attackers. The length of the Attack Type set reports the number of attack types in the data files.

• The get_attack_types method returns a list of data associated with each type of attack in a dictionary. Each key of dictionary is the name of an attack, and its value is a list of data having the same attack type. The print_attack_types method the name of each attack and the number of files that are associated with the attack; it does not print the data because of their voluminous nature. An example of its output is shown below:

```
AttackType (PIM SEND BAD REGISTER): list(dict[k]) (28 items)
AttackType (DROP VALID NEIGHBOR): list(dict[k]) (30 items)
AttackType (PIM DROP PRUNE/JOIN): list(dict[k]) (30 items)
AttackType (Bad Local Neighbor): list(dict[k]) (67 items)
AttackType (FAST HELLO): list(dict[k]) (30 items)
AttackType (PIM BAD NEXT HOP): list(dict[k]) (30 items)
```

By inspecting the output of the print_attack_types method, one can find that the input data set has 30 files having the same PIM BAD NEXT HOP attack type. To retrieve the data of these 30 files and to print out the contents of the first file, the following code is provided:

```
o = ParseIDSdata()
data_list = o.get_attack_types().get('PIM BAD NEXT HOP')
print_dict( data_list[0] )
```
• The `get_datalist` method returns an object referring to the entire structured contents of all the input files that are organized in a list of dictionaries; that is, each element of the list is a dictionary containing the data of each file. The keys of the dictionary are the names of the data blocks in an input file. The value of each key is the associated block of data which is also organized as a dictionary storing the name-value pairs of data. The following Python code illustrates the data structure by printing out all the data in the structure.

```python
for input_data in get_datalist():
    for blockname, blockdata in input_data.iteritems():
        print 'Data Block Name:', blockname
        for field, value in blockdata.iteritems():
            print '%15s = %s' % (field, value)
```

• The `extract_data` method extracts and returns a list of data according to a specified set of criteria: (1) attack type, (2) node-density type, and (3) detector type. If nothing meets all of the criteria, then it returns an empty list. Each element of the list is a dictionary. They keys of the dictionary are the names of the data blocks, and the values of the dictionary are also dictionaries, which are structures that store name-value pairs of each data block. The following Python code uses the `extract_data` method to extract a set of data that meet the given criteria and prints out the metadata information of the data.

```python
attack = 'Bad Local Neighbor'
dense = 'low_dense'
detect = 'SPARTA'
o = ParseIDSdata()
for data_dict in o.extract_data(attack, dense, detect):
    print_dict( data_dict.get(KEY_META) )
```

**Output:**

```
NODE_DENSITY : low_dense
DATE & TIME : 08-27-07_17:31
DETECTOR : SPARTA
Attacker Node : node41
Attack Type : Bad Local Neighbor
...
...
NODE_DENSITY : low_dense
DATE & TIME : 08-27-07_18:00
DETECTOR : SPARTA
Attacker Node : node27
Attack Type : Bad Local Neighbor
```
The following Python code uses the `extract_data` method to extract a set of data that meet every possible criteria and prints out their associated file names.

```python
o             = ParseIDSdata()
idsinfo       = o.get_idsinfo()
attack_types  = idsinfo.get(KEY_ATTACK_TYPE)
density_types = idsinfo.get(KEY_NODE_DENSITY)
detector_types= idsinfo.get(KEY_DETECTOR)
detector_types.add(None)
for attack in attack_types:
    for density in density_types:
        for detect in detector_types:
            data_list = o.extract_data(attack, density, detect)
            print '%s - %s - %s: (%d files)' % (
                attack, density, detect, len(data_list))
            for data_dict in data_list:
                print'	report_%s'%
                data_dict.get(KEY_META).get(KEY_DATE_TIME))
```

**Output:**

PIM SEND BAD REGISTER - high_dense - SPEC: (0 files)
PIM SEND BAD REGISTER - high_dense - SPARTA: (0 files)
DROP VALID NEIGHBOR - low_dense - None: (10 files)
    report_08-31-07_11:20
    report_08-31-07_13:57
...
    report_08-31-07_15:49
    report_08-31-07_16:05
DROP VALID NEIGHBOR - low_dense - SPEC: (0 files)
DROP VALID NEIGHBOR - low_dense - SPARTA: (0 files)
DROP VALID NEIGHBOR - medium_dense - None: (10 files)
    report_08-17-07_13:41
    report_08-17-07_13:54
...
    report_08-17-07_14:32
    report_08-17-07_14:44
Furthermore, the ParseIDSdata class also organizes the input file names according to the information in the metadata section and creates an index file containing hyperlinks to the data files. This feature is designed to provide the user a way to visually inspect an input data file. The index file can be viewed using a web browser. Appendix B shows a shorten version of an index file.

3.2 Internal Methods

This section describes and explains some internal methods in the ParseIDSdata class. Although the implementation of these methods is transparent to the user, its description is intended to assist the user in the understanding of the ParseIDSdata class, which will facilitate its improvement in the future. Another purpose is to highlight special features of the Python programming language that enable the expression of a solution in fewer lines of code. The special features are implemented in the following three functions: (1) the \texttt{filter\_data} input-data reader, (2) the \texttt{list2dict} data converter, and (3) the \texttt{print\_dict} recursive dictionary printer. Only the first two functions are part of the ParseIDSdata class.

- **Input Data Reader.** Given the name of an input data file to which the \texttt{fn} variable refers, the \texttt{filter\_data} function performs six tasks: (1) opening the data file, (2) reading its contents line by line, (3) removing any extra spaces preceding and trailing a line of text, (4) eliminating blank lines and comments, (5) placing the filtered data in a Python data structure called \texttt{list}, and (6) returning it to the caller. If the function encounters a system error, it prints out an error message, \texttt{e}, and returns an empty \texttt{list} to the caller. Completing all these tasks requires only a single line of Python code as shown below:

```python
def filter_data(fn):
    try:
        return [s for s in [ s.strip() for s in open(fn).readlines()] 
                   if len(s) and not s.startswith(COMMENT_CHAR) ]
    except IOError, e:
        print_error(e)
    return list()
```

```
• **Data Structure Converter.** Given a Python list of name-value pairs, s, the list2dict function performs four tasks: (1) splitting each name-value pair into two strings, (2) removing any extraneous white spaces surrounding the splitted strings, (3) creating a Python dictionary, and (4) returning it to the caller. Completing all these tasks requires only a single line of Python code as shown below:

```python
def list2dict(s):
    return dict([(x[0].strip(), x[1].strip())
                 for x in [x.split("=") for x in s ]])
#name=value --> [name, value] to which x refers
#  --> x[0] = name, x[1]=value
#  --> dict[name]=value
#  --> dict[x[0]]=x[1]
```

• **Dictionary Printer.** Given a Python dictionary to which the variable named d refers, the print_dict function recursively prints its key-value pairs on the screen. The function displays two formatted columns of name-value pairs: the name is on the left, and the value is on the right. The field length of the name is computed by taking the maximum value of the calculated length of each key in the dictionary. Doing so requires a single expression (max([len(x) for x in d.keys()])). The computed value is then incorporated in the output format as shown below:

```python
def print_dict(d):
    fmt='%%%ds : %%s' % max([len(x) for x in d.keys()])
    for k, v in d.iteritems():
        if type(v) == type(dict()):
            print 'Key = <%s>' % k
            print_dict(v)
        else:
            print fmt % (k, v)
    print
```

### 4. Usage Examples

This section provides three examples of Python snippets to illustrate different uses of the ParseIDSdata class. Example 1 shows a screenshot of an interactive session. Example 2 explains the code that was used to extract the values of a specific field name. Example 3 presents the code that extracts a subset of the IDS data and converts them into comma-separated values.
4.1 Example 1

This example provides snippets of Python code that uses the basic data services provided by the ParseIDSdata class to retrieve three data categories in the test data files: (1) node density, (2) attack type, and (3) detector type. The code uses the ParseIDSdata class to read in all the data files having their names beginning with “report_” in the “records” directory, which is located at the current directory (M:\MyPythonProgs\arl-wel\idsdata). The variable “o” refers to the object of type ParseIDSdata which has been instantiated successfully. The next statement, info = o.get_idsinfo(), retrieves the IDS information to which the variable “info” refers. The information is organized in a dictionary whose keys were derived from the name-value pairs in the metadata section.

```python
from parseIDSdata import *
DATDIR = 'records'
PREFIX = 'report_
BLOCK_NAME = 'CALCULATIONS LATENCY'
ATTACK_TYPE = 'PIM DROP PRUNE/JOIN'
DENSE_TYPE = 'low_dense'
FIELD_NAME = 'Attack-Jmap'
o = ParseIDSdata(DATDIR, PREFIX)
results = list()
for input_data in o.get_datalist():
    meta_data = input_data.get(KEY_META)
```

4.2 Example 2

This example shows the code necessary for computing a basic set of statistics of the values of the Attack-Jmap data field that must meet a set of two criteria: (1) the node density must be of type low_dense and (2) the attack type must be of type PIM DROP PRUNE/JOIN. Because the specified Attack-Jmap data field exists only in the CALCULATIONS LATENCY block, the whole block data must be first extracted, and then the value of the target field is extracted from the data block.

```python
from parseIDSdata import *
DATDIR = 'records'
PREFIX = 'report_
BLOCK_NAME = 'CALCULATIONS LATENCY'
ATTACK_TYPE = 'PIM DROP PRUNE/JOIN'
DENSE_TYPE = 'low_dense'
FIELD_NAME = 'Attack-Jmap'
o = ParseIDSdata(DATDIR, PREFIX)
results = list()
for input_data in o.get_datalist():
    meta_data = input_data.get(KEY_META)
```
# print_dict(meta_data)
if meta_data.get(KEY_NODE_DENSITY) != DENSE_TYPE:
    continue
if meta_data.get(KEY_ATTACK_TYPE) != ATTACK_TYPE:
    continue
block_data  = input_data.get(BLOCK_NAME)
if FIELD_NAME in block_data:
    field_value = block_data.get(FIELD_NAME)
    results.append(float(field_value))
    print '%s = <%s>' % (FIELD_NAME, field_value)

print '-----'
print 'unsorted =', results
results.sort()
print 'sorted   =', results
print '-----'
print 'max=%.3f, min=%.3f, ave=%.3f' % (results[-1], results[0], sum(results)/len(results))

Output:
Attack-Jmap = <149>
Attack-Jmap = <128>
...
Attack-Jmap = <149>
Attack-Jmap = <93>

unsorted = [149.0, 149.0, 148.0, ..., 149.0, 148.0, 93.0]
sorted   = [93.0, 128.0, 140.0, ..., 149.0, 149.0, 149.0]

max=149.000, min=93.000, ave=140.100

4.3 Example 3

This example provides a way to extract bandwidth-consumption data in "high_dense" (high node density) scenarios and save them in a comma-separated file, which is ready to be used by a spreadsheet program or by a database management system capable of importing comma-separated values. The code consists of two main functions: (1) retrieve the specified data, and (2) convert the data into comma-separated values and save them to the idsdata.csv file.

BW = 'BANDWIDTH COMSUMPTION'
TARGET_DENSITY  = 'high_dense'

def retrieve_data():
    results = list()
for data in ParseIDSdata().get_datalist():
    metadata = data.get('Metadata')
    if metadata.get('NODE_DENSITY') == TARGET_DENSITY:
        results.append(data.get(BW))
return results

def save_as_csv_file(datalist, fn):
    titles = set()
    for data in datalist:
        titles.update(data.keys())
    titles = sorted(titles)

    ofd = open(fn, 'w')
    for title in titles:
        print >> ofd, '%s,' % (title),
    print >> ofd

    for data in datalist:
        for title in titles:
            print >> ofd, '%s,' % (data.get(title)),
        print >> ofd
    ofd.close()

#-------------------------------------
data = retrieve_data()
save_as_csv_file(data, fn='idsdata.csv')

Output File Name: 'idsdata.csv'

File Contents:
AllRecTraffic, AllTransTraffic, ... minTxPms, minTxTraf,
3.2479e+05, 4.6541e+04, ... , 7832.8, 43.200,
...
5. Summary and Conclusion

The description in this report of the ProcessIDSdata class and its interfaces shows how the class is designed to read in a set of IDS data files and then organize their contents in effective data structures that are highly suitable for subsequent analysis and processing. The usage examples illustrate the built-in functions to extract a specific set of data, calculate their statistics, and view the results using a web browser. The third example illustrates the implementation of an algorithm for extracting a set of specific data and then converting them into a comma-separated file. The report also stresses some special features of the Python programming language that enable the expression of algorithmic solutions in fewer lines of code.
