Hyperthermal reactions

We have measured absolute cross sections for the reaction of ground-state O⁺ with ammonia at collision energies in the range from near-thermal to approximately 15 eV, using the guided-ion beam (GIB) method. Measurements were also performed using ammonia-d₂ to aid in mass assignments. The reaction is dominated at low collision energies by charge transfer; however, the cross section for this exothermic channel is rather small, decreasing sharply with energy from ~40 Å² for normal ammonia at near-thermal energies and leveling off at 3.7 Å² above 6 eV; the cross section is slightly smaller for ammonia-d₂. Other channels, corresponding to the production of NH₂⁺ and NO⁺, and possibly OH⁺, were detected. The NO⁺ channel, although nominally exothermic, is very small and exhibits a threshold of ~7 eV. Product recoil velocity distributions were also determined at selected collision energies, using GIB time-of-flight methods.

We have measured absolute cross section for the reaction of ground-state O⁺ with ammonia at collision energies in the range from near-thermal to approximately 15 eV, using the guided-ion beam (GIB) method. Measurements were also performed using ammonia-d₃ to aid in mass assignments. The reaction is dominated at low collision energies by charge transfer; however, the cross section for this exothermic channel is rather small, decreasing sharply with energy from ~40 Å² for normal ammonia at near-thermal energies and leveling off at 3.7 Å² above 6 eV; the cross section is slightly smaller for ammonia-d₃. Other channels, corresponding to the production of NH₂⁺ and NO⁺, and possibly OH⁺, were detected. The NO⁺ channel, although nominally exothermic, is very small and exhibits a threshold at ~7 eV. Product recoil velocity distributions were also determined at selected collision energies, using GIB time-of-flight methods.

Introduction

Hyperthermal reactions of atomic cations with ammonia are interesting both from a fundamental standpoint, in the ongoing efforts to understand the detailed mechanisms of chemical reactions, and in a broader physical sense, for example, in the quest to understand the interactions of one of the important molecules in interstellar media. Modern computational methods such as direct dynamics calculations are becoming powerful tools for studying chemistry, and benefit from having experimental benchmarks for comparison. In recent direct dynamics simulations by Sun and Schatz, excellent quantitative agreement was obtained with experiments on hyperthermal reactions of O⁺(4S) + CH₄ done in our group. Interestingly, these calculations showed, and the experiments confirmed, that many of the energetically accessible product channels were observed, including many that had not previously been seen. The aim of the present study is to provide a further basis of comparison for theoretical work.

Previous experimental investigation of the O⁺ + NH₃ system is limited to an early selected-ion flow tube (SIFT) survey in which only charge transfer was observed, occurring at a rate of 1.2 x 10⁻⁹ cm³/s. High level ab initio calculations on the lowest doublet and quartet potential energy surfaces (PESs) have been performed for O⁺ + NH₃. This work suggests that additional channels, leading to the formation of NH₂⁺ (not distinguishable in the experiment) and H₂O⁺ are accessible on the quartet PES, and that NH⁺, H₂NO⁺, and HNO⁺ derive on the doublet PES. These products, along with their ground-state energetics, are listed below with several other exothermic channels.

\[
\begin{align*}
\text{O}^+(4S) + \text{NH}_3^+ & \rightarrow \text{NH}_4^+(3A_1) + \text{OH}(^3P) & \Delta H = -3.46 \text{ eV} \\
\text{O}^+(4S) + \text{NH}_3^+ & \rightarrow \text{NH}_2^+(3B_1) + \text{OH}(^3P) & \Delta H = -2.22 \text{ eV}
\end{align*}
\]

In this paper we present the results of a guided-ion beam (GIB) study of the O⁺ + NH₃ reaction system, in which we have measured absolute cross sections for the observed reaction channels at near-thermal to hyperthermal collision energies. We have also determined recoil velocity distributions for product ions at selected collision energies. Experiments were carried out using normal and perdeuterioammonia because of the prospect of coincident ion masses.

Experimental Section

The GIB instrument used in the present study has been explained in detail previously, so only a brief description follows. The system is a tandem mass spectrometer that features a two-stage radio-frequency (rf) octopole ion guide located between the mass filters. The ion guide—collision cell assembly has been updated and is a duplicate of one described elsewhere. The first and second stages of the new ion guide are of lengths 8.6 and 19.6 cm, respectively, and the collision cell has a nominal length of 5 cm.

The O⁺(4S) beam is formed by dissociative ionization due to electron impact at ~20 eV on carbon dioxide. The primary ions are mass-selected in a Wien filter, and are injected into the first octopole at the desired kinetic energy. While in the first octopole, the ions pass through the collision cell, which is filled with the NH₃ target gas. At the exit of the collision cell, unreacted primary ions and ions produced by reactions with ammonia pass into the second octopole stage. The ions pass...
from the second octopole into a quadrupole mass filter for analysis. A ring-shaped electrode that surrounds the first octopole at the entrance of the collision cell is kept \( \sim 100 \) V above the direct current (dc) potential of the octopole, so that the small penetrating field \( (\sim 0.1 \) V) reflects thermal product ions with laboratory velocities in the backward direction, thus allowing all but a negligible number of thermal product ions to be collected and included in the determination of the absolute cross sections. Ions with higher backward laboratory velocities are similarly reflected at the octopole injection lens, except at the very lowest beam energies. The ion beam energy is known to better than \( \pm 0.1 \) eV, with \( 0.25–0.3 \) eV full width at half-maximum (fwhm) energy spread, as measured by retarding potential and time-of-flight (TOF) methods.

Secondary reactions in the collision cell occur in large part because of the very efficient rates of reaction for the thermal product ions with ammonia. These reactions are minimized by maintaining low collision cell pressures, in the range of \( 0.11–0.16 \) mTorr, by accelerating thermal ions out of the first octopole with a small (\( \sim 0.4 \) V) negative bias on the second octopole relative to the first, and by periodically turning off the rf potential to allow trapped low-energy ions to escape the octopole volume.

As in previous work, absolute cross sections are obtained by integrating the signal intensities for product and transmitted primary ions, observing the target gas pressure, and applying the Lambert–Beer expression. A correction is applied that accounts for reactions of the ion beam with the residual vacuum chamber pressure of the target gas that resides within the octopole; this correction is obtained by measuring product ion signals resulting when the target gas is diverted directly into the chamber, and typically amounts to \( 10–15\% \) of the uncorrected signal. The instrument was calibrated using the \( \text{Ar}^+ + \text{D}_2 \rightarrow \text{ArD}^+ + \text{D} \) reaction; errors in the absolute cross sections are estimated to be \( \pm 30\% \).

Product ion TOF spectra are obtained by using a pulsed \( \text{O}^+ \) beam, with a 5–6 \( \mu \)s fwhm beam pulse width, and measuring the arrival time of product ions at the detector. The pulsing frequency, here 3000 Hz, is adjusted to ensure that the bulk of product ions have sufficient time to exit the octopole, including those ions reflected by the ring electrode described above. The residual of very slow ions, which would accumulate and cause a background signal in subsequent pulse cycles, is eliminated from the octopole at the end of each cycle by briefly turning off the octopole rf voltage.

**Results**

Figures 1 and 2 show the absolute cross sections for the ionic products derived from reactions of \( \text{O}^+ \) with \( \text{NH}_3 \) and \( \text{ND}_3 \), respectively, at kinetic energies \( (E_r) \) in the range from near-thermal to \( \sim 15 \) eV. In Figure 1, the cross sections for \( \text{O}^+ + \text{NH}_3 \) derived from the SIFT thermal rate constant, attributed solely to charge transfer, and the average dipole orientation (ADO) model are shown.

The data in Figures 1 and 2 indicate that no fewer than four reaction channels occur in the \( \text{O}^+ + \text{NH}_3 \) system, the assignments of which are discussed in more detail below. As mentioned above, the difficulty in attributing the product ion masses to specific reaction channels resides in the mass coincidences among several prospective products, as well as the primary ion and secondary products. Reactions with ammonia-\( \text{d}_3 \) and TOF studies were used to address some of these issues.

Two of the observed reaction channels may be assigned unequivocally. In both Figures 1 and 2, a cross section is observed that corresponds to the production of a 30 amu product, \( \text{NO}^+ \). This channel is very small, with a cross section that does not exceed 0.3 \( \text{A}^2 \) at any point, and giving rise to no appreciable product below \( \sim 7 \) eV. At the highest energies observed, this cross section appears to diminish. The other obvious reaction product is \( \text{H}_2\text{O}^+ \), observed clearly only in \( \text{NH}_3 \) reactions since it is also a small channel and there are no coincident ions (for \( \text{ND}_3 \) reactions, \( \text{D}_2\text{O}^+ \) coincides with \( \text{ND}^+ \), a secondary product). The \( \text{H}_2\text{O}^+ \) cross section is observed only at low collision energy, where it drops sharply from \( \sim 0.8 \) \( \text{A}^2 \) to negligible levels with increasing energy.

The largest cross sections in Figures 1 and 2 involve ion products of 17 and 20 amu, respectively. The early SIFT work on normal ammonia would suggest that these correspond to charge transfer, and the energy dependence of these cross sections, with a sharp decline with energy at low collision energies and a leveling off at higher \( E_r \), is typical of exothermic charge transfer in polyatomic systems. In either case, however, there are coincident ions, namely \( \text{OH}^+ \) and \( \text{D}_2\text{O}^+ \), respectively, which are discussed below. At low energy, the \( \text{NH}_3^+/\text{OH}^+ \) cross section is \( \sim 40 \) \( \text{A}^2 \), substantially less than the SIFT and ADO results, and decreases until it levels off at a value of 3.7 \( \text{A}^2 \) above 6 eV. The \( \text{ND}_3^+ / \text{D}_2\text{O}^+ \) cross section is \( \sim 33 \) \( \text{A}^2 \) at low
energy, and levels off at 2.4 Å² at higher energy. The remaining cross section, observed in ND₃ reactions, involves product ions of mass 18 amu, possibly ND₄⁺ and/or OD⁺. This cross section is smaller than but of very similar form to the ND₃⁺/D₂O⁺ cross section, beginning at ~8 Å² at low energy, and falling to a value of 2.4 Å² at higher energy, with a slightly lower region at 2–3 eV. Obviously, this channel cannot be distinguished in NH₃ reactions since the prospective products correspond in mass either to the ion beam (NH₃⁺) or the main product (OH⁺).

The small but non-negligible signal due to secondary reactions of product ions with NH₃(ND₃) to give, largely, NH₄⁺(ND₄⁺) was treated as follows. For the ND₃ case, the secondary "cross section" was added to the 20 and 18 amu cross sections in the proportion of these cross sections. This proportional partitioning is done since the rate constants for the relevant secondary reactions have sufficient scatter among published values as to justify an approximation of their being equal, for present purposes. The same branching fraction was assumed for the NH₃ case, and was used to derive a contribution to the charge transfer cross section from the measured secondary signal. A pressure dependence study was performed at selected kinetic energies, in which the NH₄⁺ cross section was measured at a series of target gas pressures, and the results extrapolated to zero pressure; these results were found to agree with the above procedure to well within the cited error limits.

Figures 3 and 4 show TOF results at selected collision energies for the 17 amu product of O⁺ + NH₃ reactions and the 20 amu product of O⁺ + ND₃ reactions, respectively. The plots are product ion laboratory velocity distributions for the velocity component parallel to the ion beam, f(v_p), and are obtained by transforming the raw product flight time data. The thin vertical dotted line in each spectrum indicates the velocity of the center of mass of the colliding species, V_CM. This velocity comprises the origin of the center-of-mass (CM) reference frame, with faster ions corresponding to forward-scattered products (the ion beam direction being defined as "forward"), and slower ions being back-scattered. The scattering intensities in the transformed spectra are normalized to a maximum of 100.

The velocity distributions in Figure 3, at collision energies of 1.55, 2.58, and 5.15 eV, show that ions of mass 17 amu deriving from reactions with normal ammonia, i.e., NH₄⁺/OH⁺, are scattered in both the forward and backward directions. The dominant peak at low laboratory velocity in each spectrum corresponds to ions with essentially a thermal velocity distributions. The small forward scattered component diminishes at higher collision energy. The 2.58 eV plot includes a second velocity distribution (dashed curve) obtained for the same product(s) with a low octopole trapping potential, U_RF (~10 V_CM, as compared to 100 V_CM normally). This TOF spectrum, which is scaled (by eye) so that its high velocity edge overlaps the same region in the normal spectrum, exhibits a pronounced drop in relative intensity in the region near V_CM, indicating that the missing signal, due to ions not retained by the lower trapping field, is the result of wide-angle scattering as opposed to products associated with low recoil velocities in the CM frame.

The velocity distributions in Figure 4 were obtained in experiments at the same laboratory ion beam energies as in Figure 3. The TOF spectra of the mass 20 amu ammonia-d₃ products, ND₄⁺/D₂O⁺, are similar to those in Figure 3, the most remarkable difference being the slight peak in the forward scattered components in Figure 3, particularly evident at velocities just greater than 6000 and 9000 m/s in the data at E_T = 2.58 and 5.15 eV, respectively. Given that the H₂O⁺/D₂O⁺ channel is negligible (see below), and that the data in Figures 3 and 4 are otherwise similar, it is reasonable to consider whether this forward-scattered component corresponds to OH⁺. Efficient formation of OH⁺ at higher collision energies would be most likely to occur in a stripping mechanism, resulting in forward-scattered product ions. The triangles in each frame of Figure 3 indicate the nominal spectator stripping (SS) velocity, which is scaled (by eye) so that the high velocity edges of the data for normal and low U_RF overlap. The heavy dotted curve represents the difference (Δ) between the normal and low U_RF data for the forward direction.

If the forward scattered peak observed in Figure 3 is in part due to OH⁺ formation, the low-U_RF data at E_T = 2.58 eV may be used to determine an upper limit of the contribution of OH⁺ formation to the 17 amu cross section for the O⁺ + NH₃ system at this collision energy. The forward-scattered low-U_RF component represents 20% of the integrated velocity spectrum obtained at normal U_RF. The heavy dotted curve in the respective frame, labeled "Δ", is the difference between the two, and exhibits similar tailing to high velocity as seen in the O⁺ + ND₃ TOF data in Figure 4. Also noteworthy in Figures 3 and 4 is that no significant forward "superelastic" scattering is observed; the same may be expected in the backward direction for complex-mediated reactions; therefore the absolute cross sections reported above should not be substantially affected at low energy by losses in the ion guide due to products with high backward kinetic energy release.
ions are predominantly this system.' Reactions in which H$_2$O$^+$
1
expected to be a prominent product of secondary reactions in
the data), and point very clearly to the NH$_3$ data arc dominated by ions with a thermal velocity spectrum
for a substantial contribution of OD$^+$ to the 18 amu cross section
at $E_T = 2.6$ eV.

Figure 4. Laboratory velocity distributions for the ND$_3^+$/D$_2$O$^+$ (20
amu) product of O$^+$ + ND$_3$ reactions, transformed from ion TOF
measurements at the collision energies shown. In each plot, the dotted
line indicates the velocity of the CM of the collision system ($V_{CM}$).

Figure 5. The laboratory velocity distribution for the 18 amu ions
observed in the study of O$^+$ + NH$_3$ reactions at $E_T = 2.6$ eV. The
dotted line indicates the velocity of the center of mass of the collision
system ($V_{CM}$). The prominent peak at low velocity suggests that the 18
amu signal is due overwhelmingly to secondary reactions that produce NH$_3$.

Figure 5 is a velocity spectrum of 18 amu ions derived from
O$^+$ + NH$_3$ collisions at 2.58 eV collision energy. These TOF
data are dominated by ions with a thermal velocity spectrum
(the small bump at ~3000 m/s is representative of scatter in the
data), and point very clearly to the NH$_3^+$ ion, which is
expected to be a prominent product of secondary reactions in this system.\textsuperscript{10} Reactions in which H$_2$O$^+$ ions are predominantly scattered in the backward direction would be expected to occur
infrequently, given that such rebounding collisions occur only in head-on collisions. Also, low-impact parameter collisions
would be expected to be associated with high degrees of energy transfer, leading to forward scattering. Clearly, the TOF data
in Figure 5 indicate that the probability for H$_2$O$^+$ forward scattering is very small. The above-mentioned pressure depen-
dence study also suggested that the 18 amu ions observed in the
O$^+$ + NH$_3$ reactions are the result of secondary reactions, and are not due to H$_2$O$^+$.

If the normal and perdeuteroammonia exhibit similar tenden-
cies, it follows from the examination of Figure 5 that the cross
section for the 20 amu channel in Figure 2 is due to charge
transfer, yielding ND$_3^+$. The similarity of form between this
cross section and the 17 amu curve in Figure 1 suggests that
the latter is also predominantly due to charge transfer. This is
supported by the above analysis of the $E_T = 2.58$ eV TOF data in
Figure 3, which suggests that OH$^+$ is at best a minor contributor to the 17 amu signal.

The upper limit established for the OH$^+$ contribution to the
17 amu signal from O$^+$ + NH$_3$ reactions at $E_T = 2.58$ eV is
small but non-negligible. This is relevant to the assignment of the
18 amu product ions from O$^+$ + ND$_3$ reactions, shown in
Figure 2. Efforts to gain insight into the relative contributions
of ND$_3^+$ and OD$^+$ using TOF measurements (at $E_T = 1$ eV;
not shown here), in which backscattered products were the more
prevalent, were not conclusive. The suggestion of a stripping
mechanism for OH$^+$ formation and the observation of a larger
backscattered component in 18 amu products of O$^+$ + ND$_3$
reactions points to a greater contribution of ND$_3^+$ at lower
energies, while the upper limit for OH$^+$, indicated above, allows
for a substantial contribution of OD$^+$ to the 18 amu cross section
at $E_T = 2.6$ eV.

Discussion

The present study of hyperthermal reactions of O$^+$ with
ammonia indicate that several product channels occur, namely
those producing the ions NH$_3^+$, NH$_2^+$, OH$^+$, H$_2$O$^+$, and NO$^+$
eqs 1, 2, 3, 6, and 9, respectively). The H$_2$O$^+$ product (eq 5)
was below the sensitivity of the present experiment (0.1 A$^2$).

Below 9 eV, charge transfer is the largest cross section observed in this study. The cross section is substantially less
than the ADO capture cross section,\textsuperscript{13,14} and diminishes to a small value at higher collision energies. As an exothermic charge transfer process, the reaction might be expected to occur in large impact parameter collisions in which typically no momentum transfer occurs. The small cross section, particularly at large
collision energies where the capture mechanism is not relevant,
suggests that this long-range mechanism is not efficient, which
may be restated as there being only small coupling between the
entrance and exit charge transfer channels. This small coupling may be explained by the requirement that the long-
range charge transfer mechanism is quasi-resonant, and that the
magnitude of the coupling depends on the near-resonant entrance
and exit vibronic states having non-negligible Franck—Condon overlap.\textsuperscript{10} The photoelectron spectrum of ammonia\textsuperscript{17} shows that there is no Franck—Condon overlap for ionization to a state at the energy corresponding to the oxygen atom ionization potential, 13.62 eV.\textsuperscript{7}

The decline in the charge transfer cross section from its
highest point at low collision energy has an energy dependence
similar to that for the ADO model, which points to a complex-
mediated charge transfer reaction, or a capture mechanism, at
low collision energy. The TOF data in Figures 3 and 4 are
consistent with this scenario: at low energies, charge transfer
occurs largely in complex-mediated reactions, which give rise to
both backward and forward scattering; backscattering also
has a near-thermal direct contribution from long-range interactions with minimal momentum transfer. At higher collision
energies, at which the complex-lifetime is much shorter than the
rotational period, the direct mechanism dominates resulting
in predominantly backscattered product ions. The low-$U_{RF}$ product velocity distribution shown for $E_T = 2.58$ eV in Figure 3, in which the drop in signal about $V_{CM}$ indicates failure to trap products scattered at wide-angles, is also indicative of the complex-mediated mechanism as opposed to one involving a high degree of energy transfer with little kinetic energy release.

The NH$_3$/ND$_3$ reaction product is nominally the result of hydride abstraction by O$^+$ from NH$_3$/ND$_3$. Formation of the OH(OD) product could also involve discrete charge transfer and atom transfer steps. The similarity of form of the ND$_2$/OD$^+$ and charge transfer cross sections at low energies, in Figure 2, suggests that hydride abstraction competes with charge transfer. This might be expected at lower energies where the complex-mediated mechanism is observed, the complex lifetime allowing for substantial exploration of the [D, N, O]$^+$ phase space, including after charge transfer has occurred. The low contribution of OD$^+$ to the cross section at low energies, suggested above, may be expected since this channel is only slightly exothermic and may require passage through a transition state that lies above the reactants. It is interesting to note that dissociative charge transfer, giving rise to NH$_3$/ND$_3^+$ by dissociation of the charge transfer product, becomes possible at collision energies above 2.2 eV, and this may explain the perceptible rise in the ND$_2^+/OD^+$ cross section above this energy.

The issue of the relative contribution of ND$_2^+$ and OD$^+$ to the 18 amu cross section in Figure 2, unfortunately not resolved here, has broader implications. For example, if the hydride transfer channel is in fact negligible, then the TOF results in Figures 3 and 4 suggest an isotope effect that gives rise to considerably more kinetic-to-internal energy transfer in the ND$_3$ charge transfer reactions, as compared to the NH$_3$ case.

Formation of the H$_2$O$^+$ product, as per equation 6, involves the transfer of three hydrogen atoms between the heavy-atom moieties, a pathway that might be expected to occur only at low energies in a long-lived collision complex. The magnitude and energy dependence of the H$_2$O$^+$ cross section is consistent with this interpretation.

Except for the NO$^+$ channel, reaction of O$^+$ + NH$_3$ appears to yield products that are accessible on the quartet PES of the [H$_3$, N, O]$^+$ system, as calculated by Gonzalez, et al. If reaction is, in fact, constrained to the quartet PES, it may explain why several of the very exothermic reactions indicated in eqs 1 through 9 are not observed. Gonzalez et al. concluded that the reaction on the quartet surface was expected to be dominated by charge transfer, owing to the fact that transition states leading to other products are at energies above that of the charge transfer products.

The theoretical work also has interesting implications for the prospect of producing NO$^+$ in the present reaction system. Although the NO$^+$ product ostensibly may derive on an exothermic pathway in O$^+$ + NH$_3$ reactions, as indicated in eq 9, the present experiments show that this product channel gives appreciable yield only at collision energies above ~7 eV. On the quartet PES, all the observed complexes could be characterized as having relatively weak interactions between the heavy particle moieties, whereas the stable structures on the doublet PES were seen to have covalent N=O bonds. This suggests that the observed NO$^+$ product involves a crossing from quartet to doublet surface, as required by eq 9. The present experiments, however, are not conclusive on this point. Indeed, the apparent threshold for the NO$^+$ channel, at ~7 eV, is well above the collision energy required to produce this ion in its first excited state, $a^3P^+$. The formation of triplet excited NO$^+$ is spin-allowed. A similar observation was made in the reactions of N$^+$($^3S$) with H$_2$O, in which the NO$^+$ channel, which at low energies proceeds on the exothermic singlet surface, was seen to undergo a sharp rise in cross section at the collision energy corresponding to access to the spin-allowed triplet PES.

The spin conservation constraint proved important in the interpretation of the related O$^+$ + CH$_4$ reaction system. Direct dynamics calculations revealed that all the minor product channels observed for this system in experiments could be accounted for in spin-allowed reaction pathways. Another result of the O$^+$ + CH$_4$ direct dynamics work that may offer insight into the present results is that the calculations show that OH$^+$ derives from a stripping mechanism, involving large impact parameters and leading to forward scattered ions. If the small forward-scattered peaks in the present TOF data in Figure 3 are due to OH$^+$, then it is produced in O$^+$ + NH$_3$ reactions by a mechanism similar to that seen in the O$^+$ + CH$_4$ system. These calculations also indicate that products with a C=O bond form only at small impact parameter, which may hold also for the analogous NO$^+$ product in the present work.

Conclusion

We have used the GIB method to study the reactions of O$^+$($^3S$) and NH$_4$(X$^1A_1$) in the hyperthermal energy regime, obtaining absolute integral reaction cross sections as a function of collision energy from near-thermal to ~15 eV, as well as product velocity distributions at selected conditions. Reaction is dominated at lower energies ($E_T < 9$ eV) by charge transfer, the only channel previously detected for this system. Reactions with ND$_3$ allowed another major channel to be discerned, yielding ND$_2^+/OD^+$ throughout the energy range studied. Minor products also observed for this system included H$_2$O$^+$ at the lowest energies studied, and NO$^+$, a channel that turned on only at collision energies above ~7 eV, and possibly H$_2$O$^+$.

The results were discussed in light of the available theory on the O$^+$ + NH$_3$ system, however, interesting questions remain, notably the issue of whether crossing from the reactant quartet PES to a lower doublet surface is possible. Other questions that may be addressed, for example in direct dynamics studies, are the relative contributions of the NH$_2^+$/OH$^+$($^3P$)($^3P$) channels through the thermal and hyperthermal energy range, and isotope effects. It is hoped that the present study provides a stimulus and a useful benchmark for further theoretical investigations on the O$^+$ + NH$_3$ system.
