Abstract: The ability to control chromatic dispersion is in serial time encoded amplified microscopy (STEAM) where dispersion is used to slow down fast signals so that they can be digitized in real-time. Unfortunately, these dispersive elements suffer from one or more of the following restrictions: (i) limited operational bandwidth, (ii) limited total dispersion, (iii) low peak power handling, or (iv) large spatial footprint. This project was aimed at identifying new dispersive device technologies that can operate at any spectral range and with low loss. Here we report new type of tunable dispersive device, which overcomes these limitations by leveraging the large modal dispersion of a multimode waveguide in combination with the angular dispersion of diffraction gratings to create chromatic dispersion. We characterize the device’s dispersion, and demonstrate its ability to stretch a sub-picosecond optical pulse to nearly 2 nanoseconds in 20 meters of multimode optical fiber. Using this device, we also demonstrate single-shot, time-wavelength atomic absorption spectroscopy at a repetition rate of 90.8 MHz. This technology will allow STEAM based imagers, as well as other systems that exploit group velocity dispersion such as chirped pulse amplifiers, to operate at wavelengths where conventional dispersive elements are incapable of operating.

1. Introduction

Real-time measurement of fast non-repetitive events is arguably the most challenging problem in the field of instrumentation and measurement. Dispersive Fourier transformation is an emerging method that overcomes speed limitations that exist in traditional optical instruments and enables fast continuous single-shot measurements in optical sensing, spectroscopy, and imaging. Dispersive Fourier transformation maps the spectrum of an optical pulse using chromatic dispersion into a temporal waveform whose intensity mimics the spectrum and hence allows a single-pixel photodetector to capture the spectrum at a scan rate significantly beyond what is possible with conventional space-domain spectrometers. Over the last decade, this method has brought us a new class of real-time instruments that permit capture of rare events, such as rare cancer cells in blood flow, that would otherwise be missed with conventional instruments. This project was aimed at identifying new dispersive device technologies that can operate at any spectral range and with low loss.

Dispersive optical elements play critical roles in the operation of many high-bandwidth optical systems. The ability to stretch and compress optical pulses using chromatic, or group velocity, dispersion (GVD) forms the basis for chirped pulse amplification (CPA) – an indispensable technique for amplifying ultra-short optical pulses [1]. Today, the use of high-energy ultra-short laser pulses is pervasive in applications ranging from basic scientific research [2-4] to industrial material processing [5-7]. An even more ubiquitous use of GVD is dispersion compensation in high bit-rate optical communication networks, which form the backbone of the Internet. In this case, dispersion management is critical for controlling data impairment caused by optical dispersion and nonlinearities. Other important applications of GVD include intracavity dispersion compensation in modelocked lasers [8], time-wavelength spectroscopy [9, 10], time-stretch analog-to-digital conversion [11, 12], temporal imaging of optical pulses [13-16], and high-speed optical imaging [17, 18]. Unfortunately, the devices used to generate large chromatic dispersion exhibit significant tradeoffs between GVD and other performance metrics. Pairs of diffraction gratings commonly used in CPA laser systems can offer large dispersion but at the expense of footprint because the GVD scales approximately linearly with the grating separation. Dispersion compensating fiber can provide a large amount of GVD in a small footprint, but has limited power-handling capability due to its large effective optical nonlinearity. More importantly, the use of dispersion compensating fiber is limited to the near-infrared telecommunication wavelength (~1550 nm) band. At other wavelengths, commercial optical
fibers have large losses and limited dispersion. Chirped fiber Bragg gratings can produce large GVD, but suffer from similar power handling limitations due to their singlemode operation, and typically operate over a limited bandwidth within the telecommunication band.

Here, we demonstrate a new type of dispersive device that combines the spatial dispersion of diffraction gratings with the modal dispersion of a multimode waveguide to overcome the footprint, power, wavelength, and bandwidth limitations of conventional dispersive elements. This device, which may aptly be called the chromo-modal dispersion device (CMD), maps different wavelength components of an optical waveform to distinct modes of a multimode waveguide. The CMD then exploits the large modal dispersion inherent in a multimode waveguide to create chromatic dispersion (GVD).

An illustration of the generalized CMD is shown in Figure 1. A broad-bandwidth optical pulse is incident on a pair of parallel diffraction gratings, which spatially disperses and collimates the pulse spectrum. The dispersed pulse propagates through a lens, which focuses the various spectral components at a range of angles relative to the optic axis. By placing the tip of a multimode fiber at the focus of the lens, each spectral component of the pulse excites a different mode of the optical fiber. Modal dispersion in the fiber imparts either normal or anomalous GVD to the pulse, depending on the transverse alignment of the lens relative to the spatially dispersed spectrum.

![Fig. 1. Schematic diagram of the chromo-modal dispersion (CMD) device. Light is incident upon two parallel plane gratings, which disperse and collimate the optical spectrum. Angular dispersion is then applied to the spectrum using a lens. The input facet of a multimode fiber is placed at the lens focus such that the various spectral components are coupled into different fiber modes. The figure inset illustrates how different spectral components are coupled into and propagate in the multimode fiber. The dashed line represents the optic axis of the fiber. Although the configuration shown provides anomalous dispersion, the CMD can be tuned throughout both the anomalous and normal dispersive regimes by adjusting the alignment of the lens and fiber relative to the spatially dispersed spectrum.](image)

The CMD’s use of large-core multimode fiber drastically reduces the undesirable effective optical nonlinearity, making it capable of handling much larger peak optical power than singlemode fiber-based dispersive devices. Additionally, the total footprint and size of the gratings used by the CMD are orders of magnitude smaller than grating-based Treacy-geometry dispersive elements with similar dispersion. Finally, since the CMD’s operation is based on the wavelength-invariant principles of ray optics, it can operate at any wavelength for which multimode and transparent waveguides can be constructed.

## 2. Results

As a demonstration of the CMD’s functionality, we characterize its dispersion in the 800-nm wavelength band. This is an especially important wavelength band for many biological applications because of its large penetration depth in tissues, which decreases at shorter wavelengths due to Rayleigh scattering and at longer wavelengths due to water absorption. Furthermore, this wavelength band is accessible by powerful
and tunable modelocked Ti:sapphire lasers, which should enable the CMD to find use in a variety of biomedical, spectroscopic, and material processing applications.

In this work, we utilize two different implementations of the CMD (see Methods), making use of the fact that the device parameters (alignment, grating groove density, grating spacing, lens numerical aperture, fiber length, fiber numerical aperture) can be adjusted to modify its dispersive properties. To measure the dispersion of the CMD, we utilize the modulation phase shift method [19]. Using a radio-frequency lock-in amplifier as a phase-sensitive detector, we measure the relative phase shift between a 30-MHz amplitude-modulated continuous wave Ti:sapphire laser signal after it has traveled through CMD, and the reference 30-MHz signal used to drive the electro-optic modulator. By tuning the laser wavelength, we measure the wavelength-dependent phase delay of the CMD. To calculate the relative time delay (in ps) as a function of wavelength, we use the equation

$$\Delta \tau_\lambda = -\frac{\phi_\lambda - \phi_{\lambda_0}}{360f_m} \times 10^{12}$$

where $\Delta \tau_\lambda$ is the time delay of a given wavelength, $\phi_\lambda$ is the relative phase of the signal at a given wavelength measured by the lock-in amplifier, and $f_m$ is the amplitude modulation frequency. $\lambda_0$ is an arbitrary wavelength, which is chosen to have zero relative phase delay. A 3rd-order polynomial least-squares fit of the time delay data is used to calculate the dispersion parameter $D_\lambda$ using

$$D_\lambda = \frac{d\Delta \tau_\lambda}{d\lambda}.$$ 

The results of these measurements and calculations are shown in Figure 2. Additionally, to demonstrate the tunability of the CMD, we record several relative delay curves at different lateral positions of the focusing lens relative to the diffraction gratings. By maintaining alignment of the fiber tip at the lens focus, it is possible to tune the entire delay curve including zero-dispersion wavelength of the CMD. For the three alignment positions measured, the zero-dispersion wavelengths are 788.7 nm, 799.3 nm and 808.5 nm (curves 1, 2 and 3, respectively).

The CMD achieves large, tunable GVD by mapping the optical spectrum into modes of a multimode fiber. To confirm that different wavelengths occupy distinct spatial modes in the fiber, we measure the far-field mode profiles of the CMD output fiber as a function of excitation wavelength. Using the alignment position that yields the dispersion curve #1 in Figure 2(b), we record the mode profiles at various wavelengths using a CCD array placed 5 mm from the output tip of the fiber. The mode profiles for various excitation wavelengths are shown in Figure 3(a).
Fig. 3. Mode profiles at the output of the CMD fiber for alignment position #1, measured 5 mm from the output fiber facet. (a) Mode profiles recorded using various excitation wavelengths. (b) Mode profile using 745-nm excitation after propagating through 20 m of 200-mm core diameter fiber. (c) Mode profile using 745-nm excitation after propagating through 35 m of the same fiber. Blurring in the output mode profile indicates the coupling length has been reached. The scale bar in all cases is 1 mm.

Ideally, the CMD operates on the principle that individual wavelengths excite distinct modes of the multimode waveguide, each of which possesses a different propagation constant. To achieve maximum dispersion for a given waveguide length, it is important to avoid mode coupling which can result from random inhomogeneity or bends in the fiber [20, 21]. As a result, the coupling length sets an upper bound on the length of the fiber and hence the maximum dispersion. Figure 3(b) and 3(c) show the far-field mode profile of the CMD measured at the end of a 20-m and 35-m lengths of fiber, respectively (using 745-nm excitation). As shown in Figure 3(c), in the 35-m fiber the mode profile changes dramatically, indicating that the coupling length has been exceeded.

To measure the dispersive effect of the CMD on an optical pulse, we propagate pulses from a modelocked Ti:sapphire laser through the device, and monitor the fiber output using a fast photodiode (see Methods). The Ti:sapphire laser emits pulses ($\tau_{\text{FWHM}} = 80$ fs, $\lambda_{\text{center}} = 812$ nm, $\Delta\lambda = 15.8$ nm, repetition rate = 90.8 MHz) which are coupled into the CMD. By varying the alignment, the dispersion is tuned such that the entire pulse bandwidth lies in the anomalous ($D > 0$) dispersion regime (Figure 4(a)). As shown in Figure 4(b), the time-domain output’s full-width at half-maximum and full-width are 634 ps and 1.9 ns, respectively.
For comparison to the experimentally measured time-domain data, we simulated the dispersive propagation of a Gaussian optical pulse through the CMD. The simulated Gaussian pulse and CMD dispersion were chosen to have the same values as those used in the time-domain measurements. We performed the simulation by adding the appropriate spectral phase to the pulse in the frequency domain, and performing an inverse Fourier transform to return the data to the time domain. The calculated time-domain profile is denoted by the dashed curve in Figure 4(b), which is in excellent agreement with the experimental measurement. Differences between the experimental and calculated plots of the time-domain data shown in Figure 4(b) are attributed to both the use of an ideal Gaussian pulse spectrum and the use of a fit to the relative delay data, instead of the experimental values shown in Figures 4(a) and 2(a).

Loss measurements were performed by monitoring the average power before and after the grating pair, and at the output of the CMD fiber. Using a modelocked Ti:sapphire laser with the CMD in alignment position #1, the diffraction gratings’ loss was 6.0 dB. The loss due to the lens and fiber was 1.52 dB. In this case, the large grating loss is due to the use of gratings not optimized for operation at 800 nm, and can be reduced to approximately 0.4 dB by using high-efficiency dielectric gratings [22].

To demonstrate another application of the CMD in a wavelength range outside the telecommunication band, we performed real-time, single-shot [9, 23, 24] time-wavelength atomic absorption spectroscopy of the D2 (5S_{1/2} → 5P_{3/2}) transition in rubidium vapor. In this experiment, near-transform-limited pulses from a modelocked Ti:sapphire laser (λ_{center} = 780 nm, Δλ = 35 nm, repetition rate = 90.8 MHz) were transmitted through a 225-mm path length rubidium vapor cell before entering a CMD optimized for anomalous dispersion over a 4-nm bandwidth (see Methods). The optical spectrum transmitted through the CMD and the associated time-domain signals are shown in Figure 5(a) and (b), respectively. Spectra are recorded by an oscilloscope in this fashion every 11.01 ns, which is orders of magnitude faster than is possible using conventional array-detector- or scanning-based spectrometer. In addition, the effective spectrometer shutter speed, or integration time, of this measurement is equal to the optical transit time through the rubidium cell, which is approximately 750 ps. In this spectroscopy experiment, the Doppler-broadened D2 transition in rubidium generates an absorption dip in the transmission spectrum, which is observed in the time-domain profile. While it is clear from the experimental data that the CMD produces a time-wavelength mapping, it is also important to note that in this case, the amount of dispersion is sufficient to satisfy the uncertainty principle requirement for generating a dispersive Fourier transform of the wavelength-domain signal [25, 26].
3. Discussion

Fundamentally, the mode coupling length and the numerical aperture (NA) of the multimode fiber determine the maximum dispersion of the CMD. For fiber lengths shorter than the coupling length, modal dispersion dictates that the maximum output pulsewidth of the CMD can be approximated by [27]

\[
\Delta \tau_p = L \frac{N_2}{c} \left( \frac{n_1 - n_2}{n_2} \right)
\]

where \( \Delta \tau_p \) is the output pulsewidth, \( L \) is the fiber length, \( n_1 \) and \( n_2 \) are the material refractive indices of the fiber core and cladding, respectively, and \( N_2 \) is the group index of the cladding. For an input pulse with a center wavelength of 800 nm propagating in a 20-m long pure silica core fiber with a 0.37 NA, the maximum output pulsewidth is approximately 3 ns, assuming all modes of the fiber are excited. A noteworthy feature of CMD is that the output pulsewidth is independent of the input optical bandwidth, provided that it is sufficiently spatially dispersed to intercept the entire NA of the fiber after being focused by the lens. Thus, the CMD is capable of stretching small-bandwidth pulses by a large amount in a small footprint. As an example, we consider a device consisting of two 30-mm wide, 2200 line/mm gratings spaced by 10.8 cm (aligned for an angle of incidence of 50 degrees from the grating normal), a 25.4-mm diameter 0.37-NA lens, and 20-m of 0.37-NA step-index multimode fiber. For an optical pulse of 1-nm bandwidth centered at 800 nm, this CMD can provide approximately ±3000 ps of group delay, stretching an 800-nm center wavelength, 1-ps pulse to a duration of 3 ns. To achieve the same dispersion, two gratings with the same groove density placed in a double-pass Treacy geometry [28] would have to be spaced by 1400 cm, and one grating would have to be greater than 25 cm in width. The ability to impart large normal or anomalous dispersion over a small optical bandwidth makes the CMD invaluable for applications in picosecond CPA laser systems, which traditionally employ large-footprint, grating-based stretchers and compressors [28-30]. Finally, in contrast to single mode dispersive fibers, the CMD is much better at accommodating high optical power without introducing distortions caused by optical nonlinear interactions. This is a direct result of the large cross section of the multimode fiber, which reduces its effective nonlinearity. This feature can be further improved by replacing the fiber with a hollow multimode waveguide such as those previously reported [31].
As shown in Figure 3(a), the spectrum of the input pulse defines the output mode profile, which can differ significantly from the input mode. To circumvent this mode-conversion in applications such as CPA, in which the pulse stretcher and compressor spatial modes are critical, one may use a length of fiber in the CMD slightly longer than the coupling length. Coupling the modes using an extended length of fiber generates an output that consists of the sum of all fiber mode profiles (Figure 3(c)), as opposed to only modes excited initially (Figure 3(b)). Higher-order modes can subsequently be suppressed, e.g., using fiber coiling [32] or other techniques [33, 34] which reduce the output beam’s $M^2$ value.

For applications in which the output spatial mode is less important than the time-domain profile, such as in the time-wavelength spectroscopy experiment reported here, it is imperative that the CMD fiber length remains shorter than the fiber coupling length. As shown in Figure 5, the CMD generates a wavelength-to-time mapping of the optical spectrum used to probe the $D_2$ transition in rubidium vapor in real-time. Nonlinearity in this mapping can be attributed to the shape of the CMD’s dispersion curve, which is fundamentally the same as that shown in Figure 2(b), albeit over a bandwidth of ~4 nm. This nonlinearity in the CMD’s dispersion slope is static and deterministic, and hence, it can be compensated using digital post-processing [35-37]. Thus, knowledge of the CMD dispersion combined with the appropriate laser source and detector will enable high spectral resolution, real-time spectroscopy at any wavelength for which the fiber is transparent or a hollow waveguide can be constructed.

4. Conclusion

In summary, we have demonstrated and characterized a compact device that produces large and tunable group velocity dispersion. This has been achieved by transforming the large modal dispersion of a multimode fiber into chromatic dispersion. The amount of dispersion as well as the zero dispersion wavelength is tunable and produces normal or anomalous dispersion, with maximum dispersion limited only by the coupling length and NA of the multimode fiber used. As a proof of concept demonstration, we stretch a sub-picosecond optical pulse to nearly 2 ns in 20 m of multimode optical fiber. By adjusting the grating groove density and separation, The CMD can be configured to accommodate larger or smaller bandwidth pulses, while maintaining the same output pulse width. To demonstrate one of its utilities, we demonstrated single-shot atomic absorption spectroscopy of rubidium vapor. The large dispersion and small footprint of the device make the CMD potentially useful for on-chip dispersion compensation using optical components such as integrated gratings and planar multimode waveguides. The CMD’s physical compactness, combined with the magnitude and tunability of its dispersion suggest its use as a versatile tool for pulse stretching or compression in a variety of applications in which the capabilities of singlemode fiber or diffraction grating-based dispersive elements will not suffice. It will allow STEAM based imagers, as well as other systems that exploit group velocity dispersion such as chirped pulse amplifiers, to operate at wavelengths where conventional dispersive elements are incapable of operating.

5. Methods

The CMD used in all experiments except for absorption spectroscopy is constructed from a pair of 900-grooves/mm ruled diffraction gratings spaced 14 cm apart, a $f = 35$ mm, 25.4-mm diameter, antireflection-coated achromatic doublet lens, and a 20-m long, 200-mm diameter core, 0.37-NA step-index pure silica core, polymer cladding multimode optical fiber. The lens and fiber are mounted on the same linear translation stage, such that as the transverse alignment of the lens is altered, the fiber tip remains at the focus of the lens. Modulation phase shift measurements were performed using a custom-built continuous wave Ti:sapphire laser. The laser linewidth full width at half maximum for each measurement point was less than 0.20 nm. The RF lock-in amplifier time constant was set to 1 second for all measurements. Time-domain measurements were performed by connecting an unamplified InGaAs photodiode with a 25-ps impulse response time to the output of the CMD. Electrical signals from the photodiode are recorded using a 50-gigasample/s, 16-GHz analog bandwidth oscilloscope. Real-time atomic absorption spectroscopy was performed on a heated 75-mm length rubidium vapor cell (natural isotope mixture) in a triple-pass geometry. A narrow bandpass filter ($\Delta \lambda = 3$ nm) centered at 780-nm was placed after the rubidium cell to limit the optical bandwidth entering the CMD. The CMD configuration used in this experiment consisted of two 30-mm length, 2000 grooves/mm ruled diffraction gratings spaced by 28 cm. The lens and fiber were the same as used in all other experiments.
