Abstract

In this paper an analysis of remote atmospheric magnetometry concepts, using molecular oxygen as the paramagnetic species is considered. The objective is to use these mechanisms for the remote detection of underwater and underground objects. We use the coupled Maxwell-density matrix system of equations to describe the magnetization of the paramagnetic species in the presence of an intense modulated laser pulse and ambient magnetic field. The magnetic dipole transition line that is considered is the $b^1\Sigma_g^+ \rightarrow X^3\Sigma_g^-$ transition band of O$_2$ near 762 nm. The pump is taken to be a high-intensity, pulsed, polarized titanium-doped sapphire laser. The model is used to investigate a magnetic anomaly detection signature using the polarization rotation of the wakefield behind the pump pulse. The major challenges are the collisional dephasing of the atmospheric oxygen transitions and the strength of the effective magnetic dipole interaction.
I. Introduction

Optical magnetometry is a highly sensitive method for measuring small variations in magnetic fields [1-3]. The development of a remote optical magnetometry system would have important applications for the detection of underwater and underground objects that perturb the local ambient magnetic field. In our remote atmospheric optical magnetometry model, a high-intensity laser pulse is employed to drive the magnetic spin precession in the presence of the earth’s magnetic field. Zeeman splitting of the molecular energy levels and consequently the precessional frequency are proportional to the local magnetic field. This can, in principle, provide a precise means to measure variations in the Earth’s magnetic field. For a number of magnetic anomaly detection (MAD) applications, μG magnetic field variations must be detected at standoff distances of approximately one kilometer from the sensor [4].

In this paper we consider atmospheric molecular oxygen as the paramagnetic species in a nonlinear remote optical magnetometry configuration depicted Fig. 1. The propagation of the high-intensity pump laser pulse to remote (~ km) detection sites is considered. By employing the optical Kerr effect we show that high laser intensities (10^{12} W/cm^2) can be propagated to remote locations. Using a high-intensity polarized laser pulse we consider the polarization rotation of the wakefield behind the pump pulse. The pump intensity is limited (< 10^{12} W/cm^2) to avoid photoionization processes.

![Diagram of Remote Nonlinear Optical Magnetometry Configuration](image)

Figure 1: Remote nonlinear optical magnetometry configuration. The Earth’s magnetic field is $B_o \approx 0.5G$ and $\delta B$ is the perturbation caused by the underwater/underground object.

Molecular oxygen’s paramagnetic response is due to two unpaired valance electrons. The ground state of oxygen $X^3\Sigma_g^-$, commonly referred to as “triplet oxygen,” has total angular
momentum \( J = 1 \), total spin \( S = 1 \) and three degenerate sublevels. The excited upper state being considered is denoted by \( b^1\Sigma_g^+ \). It has \( J = 0 \) and is a spin singlet \( S = 0 \) state with only one sublevel. The upper state can undergo three radiative transitions, \( b^1\Sigma_g^+ \rightarrow X^3\Sigma_g^- (m = \pm 1) \), \( b^1\Sigma_g^+ \rightarrow X^3\Sigma_g^- (m = 0) \), but the latter is insignificant because it is an electric quadruple transition. There is an intermediate state, referred to as \( a^1\Delta_g \), into which the excited \( \text{O}_2 \) molecule can decay and is discussed in Appendix A. The \( \text{O}_2 \) transition line being considered is the \( b^1\Sigma_g^+ \rightarrow X^3\Sigma_g^- \) transition band of oxygen near 762 nm. In the low laser intensity, long pulse, regime this transition has been investigated theoretically [5,6] and experimentally [7] and is a prominent feature of air glow.

In this paper, a high intensity, polarized titanium-doped sapphire laser is considered for the pump laser. These lasers have an extremely large tuning range from 660 nm to 1180 nm, and can have linewidths that are transform limited. A major challenge for this, as well as any remote atmospheric optical magnetometry concept, is collisional dephasing (elastic collisions) of the transitions. The elastic molecular collision frequency, at standard temperature and pressure (STP), is \( \gamma_c = N_{\text{air}} \sigma v_{th} = 3.5 \times 10^9 \text{ sec}^{-1} \), where \( \sigma \) is the molecular cross section and \( v_{th} \) is the thermal velocity [7]. On the other hand, the Larmor frequency (spin precession) in the Earth’s magnetic field, \( B_o \approx 0.5 \text{ G} \), is \( \Omega_o = qB_o/(2mc) \approx 4.5 \times 10^6 \text{ rad/sec} \) (\( h\Omega_o = 3 \times 10^{-9} \text{ eV} \)), where \( m \) and \( q \) are the electron mass and charge and \( c \) is the speed of light. Since the dephasing frequency is far greater than the Larmor frequency, the parameters are somewhat restrictive for remote atmospheric magnetometry. However, rotational magnetometry experiments based on molecular oxygen at STP and magnetic fields of \( \sim 10 \text{ G} \) have shown measurable linear Faraday rotational effects [7].

II. Atmospheric Propagation of Intense Laser Pulses (Focusing & Compression)

The magnetic anomaly detection concepts considered here rely on propagation of intense laser beams in the atmosphere. Atmospheric propagation of intense, short pulse lasers are strongly affected by various interrelated linear and nonlinear processes [8]. These include diffraction, Kerr focusing, group velocity dispersion, spectral broadening and self-phase modulation. Pulse compression can be achieved by introducing a frequency chirp on the pulse; however, for the problem under consideration, pulse compression is not significant. Nonlinear transverse focusing results from the Kerr effect. In general, a laser pulse propagating in air can be longitudinally and transversely focused at remote distances (> km) to reach high intensities \( \sim 10^{12} \text{ W/cm}^2 \), as indicated in Fig. 2.
Here we present the model describing longitudinal and transverse compression of a chirped laser pulses in air [8]. For optimally chosen parameters, the longitudinal and transverse focal distances can be made to coincide resulting in a rapid intensity increase near the focal region.

The laser electric field is given by \( \hat{E}(r, \eta, \tau) = (1/2)\hat{\mathbf{E}}(r, \eta, \tau)e^{-i\omega \tau} + \text{c.c.} \), where \( \hat{E} \) is the complex amplitude, \( \omega \) is the frequency, \( r \) is the radial coordinate, \( \tau = t - z/c \) and \( \eta = z \) are the transformed coordinates, the propagation distance \( z \) and time \( t \) are in the laboratory frame. Substituting this field representation into the wave equation results in a higher order paraxial wave equation for \( \hat{E}(r, \eta, \tau) \) [8],

\[
\left[ \nabla_{\perp}^2 + 2ik \frac{\partial}{\partial \eta} - c^2 k^2 \beta_2 \frac{\partial^2}{\partial c^2 \tau^2} + \frac{\omega^2 n_k}{4\pi c} |\hat{E}(r, \eta, \tau)|^2 \right] \hat{E}(r, \eta, \tau) = 0, \tag{1}
\]

where the wavenumber is \( k = \omega/c \) and the group velocity dispersion parameter is \( \beta_2 = 2.2 \times 10^{-31} \text{sec}^2/\text{cm} \). The nonlinear refractive index of air is \( n = 1 + n_k I \), where the Kerr nonlinear index is \( n_k = 3 \times 10^{-19} \text{cm}^2/\text{W} \) and \( I \) is the laser intensity. The values for \( \beta_2 \) and \( n_k \) apply to air at STP and \( \lambda = 2\pi/k \approx 762 \text{nm} \).

Equation (1) can be solved by assuming the pulse is described by a form that depends on certain spatially-dependent parameters. With this assumption, a set of simplified coupled equations can be derived for the evolution of the spot size, pulse duration, amplitude and phase of the laser field. Taking the laser pulse to have a Gaussian shape in both the transverse and longitudinal directions, the complex amplitude can be written as

\[
\hat{E}(r, \eta, \tau) = E_\circ(\eta)e^{i\theta(\eta)}e^{-(1+i\alpha(\eta))r^2/R^2(\eta)}e^{-(1+i\beta(\eta))\tau^2/T^2(\eta)}, \tag{2}
\]
where $E_0(\eta)$ is the field amplitude, $\theta(\eta)$ is the phase, $R(\eta)$ is the spot size, $\alpha(\eta)$ is related to the curvature of the wavefront, $T(\eta)$ is the laser pulse duration, and $\beta(\eta)$ is the chirp parameter. The quantities $E_0$, $\theta$, $T$, $R$, $\alpha$, $\beta$ are real functions of the propagation distance $\eta$. The instantaneous frequency spread along the pulse, i.e., chirp, is $\delta \omega(\eta, \tau) = 2\beta(\eta)\tau / T^2(\eta)$, where $\beta(\eta) = T(\eta) / (2\beta_z) \partial T(\eta) / \partial \eta < 0 (> 0)$ results in a negative (positive) frequency chirp, i.e., frequency decreases (increases) towards the back of the pulse.

Substituting Eq. (2) into Eq. (1) and equating like powers of $r$ and $\tau$, the following coupled equations for $R$ and $T$ are obtained,

$$\frac{\partial^2 R}{\partial \eta^2} = \frac{4}{k^2 R^3} \left( 1 - \frac{E_0}{P_{NL}} \frac{1}{T} \right),$$

$$\frac{\partial^2 T}{\partial \eta^2} = \frac{4\beta_z E_0}{k P_{NL}} \frac{1}{R^2 T^2} + \frac{4\beta_z^2}{T^3},$$

where $E_0 = P(0)T(0)$ is proportional to the laser pulse energy and is independent of $\eta$, $P(\eta) = \pi R^2(\eta) I(\eta) / 2$ is the laser power, $I(\eta) = c E_0^2(\eta) / (8\pi) = I(0) R^2(0) T(0) / (R^2(\eta) T(\eta))$ is the peak intensity and $P_{NL} = \lambda^2 / (2\pi n_\lambda)$ is the self-focusing power. In Eq. (3) the initial conditions are given by $\alpha(0) = -(kR(0) / 2) \partial R(0) / \partial \eta$ and $\beta(0) = T(0) / (2\beta_z) \partial T(0) / \partial \eta = 0$.

The first term on the right hand side of Eq. (3a) describes vacuum diffraction while the second term describes nonlinear self-focusing, i.e., due to $n_K$. Nonlinear self-focusing dominates diffraction resulting in filamentation when $P > P_{NL} \approx 3$ GW [8,9].

In the limit that the pulse length does not change appreciably the laser spot size is given by $R(\eta) = R(0) \left[ 1 - 2\alpha(0) \eta / Z_{R0} + (1 - P / P_{NL} + \alpha^2(0))(\eta / Z_{R0})^2 \right]^{1/2}$, where $Z_{R0} = k R^2(0) / 2$ is the Rayleigh length. The spot size reaches a focus in a distance $\eta / Z_{R0} = \alpha(0) / \left( 1 - P / P_{NL} + \alpha^2(0) \right)$ as long as $P < (1 + \alpha^2(0))P_{NL}$.

Figures 3(a) and 3(b) show the evolution of the laser spot size and the intensity as a function of propagation distance for $\lambda = 762$ nm. At focus, the laser intensity $(I_{focus} = 6 \times 10^{10}$ W/cm$^2$) and spot size ($R_{focus} = 1.3$ mm) are held constant by choosing appropriate initial conditions: wavefront curvature $\alpha(0) = 37$, pulse duration $T(0) = 100$ psec, and chirp $\beta(0) = 0$. By changing the laser energy and the initial spot size, the nonlinear self-focusing effect changes the focal point from 0.25 km to 0.75 km (see Fig. 3). Nonlinear laser pulse propagation allows for moving of the detection site location.
Figure 3: Evolution of (a) laser spot size and (b) normalized peak laser intensity as functions of propagation distance for different initial laser energies and spot sizes. The laser energy and initial spot size for the solid, dashed, and dotted lines are $E_o = 100, 150, 190 \text{ mJ}$ and $R(0) = 4.7, 6.7, 8.2 \text{ cm}$, respectively.

III. Optical Magnetometry Model

The four levels of $O_2$ being considered in the magnetometry model are shown in Fig. 4. The ground state is split by the Zeeman effect into three levels $|1\rangle$, $|2\rangle$, and $|3\rangle$ and the excited state is denoted by $|4\rangle$. The magnetic quantum number $m$ associated with the various levels is indicated in Fig. 4. The excited state, level $|4\rangle$, can be populated by right hand polarized (RHP) light from level $|3\rangle$ or by left hand polarized light (LHP) light from level $|1\rangle$. Here the quantization axis and the direction of the static magnetic field are taken to be along the direction of laser propagation, $z$ – axis. Circularly polarized radiation carries angular momentum $\pm \hbar$ which is directed along the propagation direction, hence the selection rule for allowed transitions is $\Delta m = \pm 1$, which will conserve angular momentum [10]. It should be noted that this transition is strictly magnetic dipole- and spin-forbidden, but spin-orbit coupling between the $b^1\Sigma_g^+$ and $X^3\Sigma_g^- (m = 0)$ states leads to a transition with a magnetic dipole-like nature and a larger than expected dipole moment [5,6,11].
Figure 4: Energy levels associated with the ground and excited state of O₂. The transition frequency corresponds to ~ 762 nm ($\hbar \omega_A = 1.63 \text{ eV}$). The Zeeman splitting of the ground state is caused by the ambient magnetic field.

A high-intensity pump pulse generates a magnetization current density $J_M = c \nabla \times M$, where $M$ is the magnetization field. The current density in turn generates a response electric field and can also modify the pump pulse. The response electric field $E$ is given by (Gaussian units) $(\nabla^2 - (1/c^2) \partial^2 / \partial t^2)E = (4\pi / c^2) \partial J_M / \partial t = (4\pi / c) \partial (\nabla \times M) / \partial t$. The magnetization is represented by a sum of RHP and LHP components $M(z,t) = M_R(z,t) \hat{e}_R + M_L(z,t) \hat{e}_L + \text{c.c.}$, where $M_R(z,t) = N \mu_m \rho_{43}(z,t)$, $M_L(z,t) = N \mu_m \rho_{41}(z,t)$, $N$ is the density of the paramagnetic species (oxygen molecules), $\mu_m$ is the effective magnetic dipole moment associated with the transitions, $\rho_{43}$ and $\rho_{41}$ are the off-diagonal coherence of the allowed density matrix elements (see Fig. 4) and $\hat{e}_{R,L} = (\hat{e}_x \pm i \hat{e}_y) / 2$ are vectors denoting the polarization direction. The magnetization current density can be written as $J_M = -ic \partial M_R(z,t) / \partial z \hat{e}_R + ic \partial M_L(z,t) / \partial z \hat{e}_L + \text{c.c.}$ In terms of the x and y components, $J_M = -ic(2/c) \partial (M_R - M_L) / \partial z \hat{e}_x + ic(2/c) \partial (M_R + M_L) / \partial z \hat{e}_y + \text{c.c.}$

The density matrix equation is given by $[10,12,13] \partial \rho_{nm} / \partial t = -i \omega_{nm} \rho_{nm} + \sum_i \{ \Omega_{ni} \rho_{in} - \Omega_{im} \rho_{in} \} + \text{relaxation terms}$, where $\omega_{nm} = \omega_n - \omega_m$, $\Omega_{nm}$ denotes the interaction frequency, the phenomenological relaxation terms are due to elastic and inelastic collisions, and spontaneous transitions and the magnetic dipole interaction Hamiltonian is $-\mathbf{\mu}_m \cdot \mathbf{B}$ (Appendix B). The off-diagonal coherence elements of the density matrix for the relevant transitions ($|1\rangle \rightarrow |4\rangle$ and $|3\rangle \rightarrow |4\rangle$) are given by
\[ \begin{align*}
\dot{\rho}_{41}/\dot{t} &= -\gamma_c \rho_{41} - i\omega_{41} \rho_{41} + i\Omega_{41} (\rho_{11} - \rho_{44}) + i\Omega_{43} \rho_{31}, \\
\dot{\rho}_{43}/\dot{t} &= -\gamma_c \rho_{43} - i\omega_{43} \rho_{43} + i\Omega_{43} (\rho_{33} - \rho_{44}) + i\Omega_{41} \rho_{13},
\end{align*} \]

where \( \gamma_c \) is the elastic collision frequency (not population transferring), the full set of density matrix equations are given in Appendix B.

The pump laser field, which induces the magnetization field, is expressed as a sum of RHP and LHP fields

\[ \mathbf{B}_{\text{pump}}(z,t) = B_R(z,t)\hat{\mathbf{e}}_R + B_L(z,t)\hat{\mathbf{e}}_L + \text{c.c.}, \]

where \( B_{R,L}(z,t) = \hat{B}_{R,L}(z,t)e^{i\psi(z,t)} \) and \( \psi(z,t) = kz - \omega t \). The interaction frequencies associated with the allowed transitions are

\[ \Omega_{43} = \mu_m B_R(z,t)/\hbar = \hat{\Omega}_R(z,t)e^{i\psi(z,t)} \quad \text{and} \quad \Omega_{41} = \mu_m B_L(z,t)/\hbar = \hat{\Omega}_L(z,t)e^{i\psi(z,t)}, \]

where \( \hat{\Omega}_{R,L} = \mu_m \hat{B}_{R,L}/\hbar \) is (half) the Rabi frequency associated with the RHP and LHP components of the pump. Note that the Rabi frequency is defined with respect to the peak field.

Although we are considering a magnetic dipole transition it is convenient to express the Rabi frequency normalized to an electric dipole moment. The magnitude of the Rabi frequency can be written as

\[ \hat{\Omega}_{\text{Rabi}} = \mu_m \hat{B}_{\text{peak}}/\hbar = (\mu_m / \mu_e) (\mu_e \hat{E}_{\text{peak}}/\hbar) = (\mu_m / \mu_e) (\mu_e / \hbar)(8\pi I/c)^{1/2}, \]

where \( I = c \hat{E}_{\text{peak}}^2 / (8\pi) \) is the pump laser intensity and \( \hat{E}_{\text{peak}} \) is the peak field. Taking the normalizing electric dipole moment to be \( \mu_e = q r_h = 2.5 \times 10^{-18} \text{ statC-cm} \), where \( r_h \) is the Bohr radius the magnitude of the Rabi frequency is \( \hat{\Omega}_{\text{Rabi}} \left[ \text{rad/sec} \right] = 2.5 \times 10^8 (\mu_m / \mu_e) \sqrt{[\text{W/cm}^2]}. \) As an example, for \( I = 10^{11} \text{ W/cm}^2 \) and \( \mu_m / \mu_e = 10^{-4} \), the Rabi frequency is \( \hat{\Omega}_{\text{Rabi}} = 8 \times 10^9 \text{ rad/sec}. \)

### IV. Faraday Rotation of Wakefields Driven by Intense Laser Pulses

The incident pump field is taken to be polarized in the x-direction

\[ \mathbf{E} = \hat{E}_0(z,t)e^{-i(kz - \omega t)}(\hat{\mathbf{e}}_R + \hat{\mathbf{e}}_L) + \text{c.c.}, \]

where \( \omega \) is the carrier laser frequency and the complex pulse amplitude \( \hat{E}_0(z,t) \) can be modulated. Employing the variables \( \tau = t - z/c \) and \( \eta = z \),

\[ \mathbf{E} = \hat{E}_0(\tau)e^{-i\tau} e^{ik\eta} (\hat{\mathbf{e}}_R + \hat{\mathbf{e}}_L) + \text{c.c.}, \]

the corresponding magnetic field in the y-direction is

\[ \mathbf{B} = -i \hat{E}_0(\tau)e^{-i\tau} e^{ik\eta} (\hat{\mathbf{e}}_R - \hat{\mathbf{e}}_L) + \text{c.c.}, \]

where \( \Delta k = k - \omega / c \approx 2\pi i k N\mu_m^2 \rho_{11}/(\hbar \gamma_e) \) is the wavenumber mismatch (damping) obtained from the linear dispersion relation. The characteristic wavenumber mismatch for \( \lambda = 762 \text{ nm} \) at atmospheric molecular oxygen density \( N = 5.7 \times 10^{18} \text{ cm}^{-3} \) and an equilibrium population of \( \rho_{11} = 1/3 \) is \( i\Delta k = -\Gamma_D = -1.7 \times 10^3 \text{ cm}^{-1} \) \((1 / \Gamma_D \approx 6 \text{ m})\). As the pulse propagates through the atmosphere it induces a magnetization current which generates a field polarized in both the x and y directions. The wave equation for the forward propagating, y-component of the complex field amplitude is
\( (\partial / \partial \eta + i \Delta k) \hat{E}_\eta(\eta, \tau) = -i 2\pi N \mu_m k (\hat{\rho}_{43}(\tau) + \hat{\rho}_{41}(\tau)) \), where the Faraday rotated field is \( \hat{E}_\eta(\eta, \tau) e^{-i \omega \tau} e^{i \Delta k \eta} \hat{E}_\eta + c.c. \). The magnetization current is a function of the off-diagonal coherence terms of the density matrix elements \( \rho_{43}(\eta, \tau) = \hat{\rho}_{43}(\tau) e^{-i \omega \tau} e^{i \Delta k \eta} \) and \( \rho_{41}(\eta, \tau) = \hat{\rho}_{41}(\tau) e^{-i \omega \tau} e^{i \Delta k \eta} \). The slowly varying quantities \( \hat{\rho}_{43}(\tau) \) and \( \hat{\rho}_{41}(\tau) \) are given by reduced density matrix equations \( (\partial / \partial \tau - i \Delta \omega_{43}) \hat{\rho}_{43}(\tau) = i \hat{\Omega}_{43}(\tau) \rho_o \) and \( (\partial / \partial \tau - i \Delta \omega_{41}) \hat{\rho}_{41}(\tau) = i \hat{\Omega}_{41}(\tau) \rho_o \), where \( \hat{\Omega}_{43}(\tau) = -i \mu_m \hat{E}_o(\tau) / \hbar \), \( \hat{\Omega}_{41} = i \mu_m \hat{E}_o(\tau) / \hbar \), \( \rho_o = \rho_{31} = \rho_{22} = \rho_{33} = 1 / 3 \), \( \rho_{44} = 0 \), \( \Delta \omega_{nm} = \omega - \omega_{nm} + i \gamma_c \), \( \omega_{43} = \omega_A - \Omega_o \), \( \omega_{41} = \omega_A + \Omega_o \) and it has been assumed that \( c|\Delta k| / \omega \| 1 \).

In the case where the pump amplitude is not modulated in amplitude or frequency, i.e., conventional Faraday rotation within a long pump duration, \( \partial / \partial \tau = 0 \), the spatial change in the Faraday rotated field is given by \( \frac{d}{d \tau}(\hat{E}_\eta(\eta, \tau)) = 2\pi k N \mu_m^2 \hat{E}_o(\tau) / \hbar \rho_o \Omega_o / \gamma_c^2 \). After propagating a distance \( L \), the ratio between the Faraday rotated and incident intensities is \( I_y / I_o = |E_y|^2 / |E_o|^2 = (2\pi)^4 (L / \lambda)^2 (N \mu_m^2 \rho_o / \hbar) \Omega_o / \gamma_c^2 \).

In the present model the pump pulse consists of a pulse train, as shown in Fig. 5, in which the duration of the individual micropulses, denoted by \( \tau_p \), can be comparable or longer than the damping time \( 1 / \gamma_c \). However, the time separation between the micropulses \( T \) is taken to be long compared to a damping time. With this ordering of timescales the individual pump pulses excite the density matrix elements \( \rho_{43} \) and \( \rho_{41} \) which generate a wakefield that decays behind the individual pump pulses (Fig. 5). The magnetization currents generate a Faraday rotated wakefield behind each pump pulse.
The general form of the off-diagonal coherence elements is
\[
(\partial / \partial \tau - i \Delta \omega_{nm}) \hat{\rho}_{nm}(\tau) = i \hat{\Omega}_{nm}(\tau) \rho_o
\]
with solution
\[
\hat{\rho}_{nm}(\tau) = i \rho_o \int_0^\tau d\tau' \hat{\Omega}_{nm}(\tau') \exp(-i \Delta \omega_{nm}(\tau' - \tau))
\]
within the pump pulse. The solution behind the pump pulse is
\[
\hat{\rho}_{43}(\tau) = \hat{\rho}_{43}(\tau_p) \exp(i \Delta \omega_{43}(\tau - \tau_p)) \quad \text{and} \quad \hat{\rho}_{41}(\tau) = \hat{\rho}_{41}(\tau_p) \exp(i \Delta \omega_{41}(\tau - \tau_p))
\]
The reduced wave equations for the x and y components of the wakefields are
\[
(\partial / \partial \eta + i \Delta k) \hat{E}_x(\eta, \tau) = -2\pi / c \hat{J}_{Mx}(\tau) = -C_o k \rho_o \omega W_x(\tau) \hat{E}_o,
\]
\[
(\partial / \partial \eta + i \Delta k) \hat{E}_y(\eta, \tau) = -2\pi / c \hat{J}_{My}(\tau) = i C_o k \rho_o \omega W_y(\tau) \hat{E}_o,
\]
where \(k = \omega / c\), \(\omega >> |\partial / \partial \tau|, c|\Delta k|\) and \(C_o = 2\pi (N \mu_m^2 / \hbar \gamma_c) / \gamma_c \approx 6 \times 10^{-7}\) is a unitless parameter. In estimating \(C_o\) we have taken the magnetic dipole moment to equal \(\mu_m = \mu_e \times 10^{-4} = 2.5 \times 10^{-22}\) statC-cm, the collision frequency to be \(\gamma_c = 3.5 \times 10^9\) sec\(^{-1}\) and the \(O_2\) density to be \(N = 5.7 \times 10^{18}\) cm\(^{-3}\). The current densities are \(\hat{J}_{Mx}(\tau) = (N \mu_m \omega / 2)(\hat{\rho}_{43}(\tau) - \hat{\rho}_{41}(\tau))\) and \(\hat{J}_{My}(\tau) = -(N \mu_m \omega / 2)(\hat{\rho}_{43}(\tau) + \hat{\rho}_{41}(\tau))\), behind the pulse (\(\tau \geq \tau_p\)) they are given by
\[
\hat{J}_{Mx}(\tau) = \left( N \mu_m^2 \omega \rho_o \right) \frac{\omega \gamma_c}{\Omega_o^2 + \gamma_c^2} W_x(\tau),
\]
\[
\hat{J}_{My}(\tau) = -i \left( N \mu_m^2 \omega \rho_o \right) \frac{\omega \gamma_c}{\Omega_o^2 + \gamma_c^2} W_y(\tau),
\]
where the time dependence of the wakefield is captured by

\[
W_x(\tau) = e^{-\gamma_c (\tau - \tau_p)} \left[ \cos(\Omega_o (\tau - \tau_p)) - e^{-\gamma_c \tau_p} \cos(\Omega_o \tau) - (\Omega_o / \gamma_c) \left( \sin(\Omega_o (\tau - \tau_p)) - e^{-\gamma_c \tau_p} \sin(\Omega_o \tau) \right) \right],
\]

(7a)

\[
W_y(\tau) = e^{-\gamma_c (\tau - \tau_p)} \left[ \sin(\Omega_o (\tau - \tau_p)) - e^{-\gamma_c \tau_p} \sin(\Omega_o \tau) + (\Omega_o / \gamma_c) \left( \cos(\Omega_o (\tau - \tau_p)) - e^{-\gamma_c \tau_p} \cos(\Omega_o \tau) \right) \right].
\]

(7b)

Figure 6: (a) x-component and (b) y-components of the wakefield response functions \( W_{x,y}(\tau) \) behind the pulse for \( \Omega_o = 4.5 \times 10^6 \text{ rad/s} \). The pulse durations for the solid, dashed, and dotted lines are \( \tau_p = 0.1 \text{ ns}, 0.5 \text{ ns}, 1 \text{ ns} \), respectively.

Figure 6 shows the wakefield time dependence, Eqs. (7), for pump pulse durations of \( \tau_p = 0.1, 0.5, \) and 1 nsec, pump pulse energy of 100 mJ, and spot size of 1 mm. This results in a range of pump intensities from \( 6 \times 10^9 \text{ W/cm}^2 \) to \( 6 \times 10^{10} \text{ W/cm}^2 \). Equations (5) indicates that \( \hat{E}_{x,y} / \hat{E}_o \) is proportional to \( W_{x,y}(\tau) \), if \( \Delta k \) is neglected. For the parameters in Fig. 6, the normalized peak wakefield amplitudes are \( \left| \hat{E}_x / \hat{E}_o \right| \approx 0.5, 1.5, \) and 1.6 and \( \left| \hat{E}_y / \hat{E}_o \right| \approx 1 \times 10^{-4}, 1.2 \times 10^{-3}, \) and \( 2 \times 10^{-3} \). There is a tradeoff between driving the wakefields with a higher
intensity pump \( \hat{E}_o \sim \tau_p^{-1/2} \) versus driving it for a longer duration \( W_{x,y} \sim \tau_p \). As a result, for \( \tau_p > 3/\gamma_c \) the wakefield amplitude begins monotonically decreasing.

For remote magnetic anomaly detection small spatial differences in the magnetic field must be measured. Here we consider measuring the differences in wakefield intensities at two nearby locations. The locations are referred to as (1) and (2) and have local magnetic fields \( B_o \) and \( B_o + \delta B \). The intensity of the wakefield at location (1) and (2) is \( I_1 \) and \( I_2 \), respectively. The fractional change in intensity of the y-polarized wakefield is \[
\frac{|I_1 - I_2|}{I_1} = |\delta I|/I_1 \approx 2|\delta \hat{E}_y / \hat{E}_{1y}|,
\] where \( \hat{E}_{1y} \) is the y-component of the wakefield amplitude and \( \delta \hat{E}_y \) is the difference in the wakefield amplitudes between the two locations. Figure 7 shows the fractional wakefield intensities for various values of \( \delta B \). For the values shown, \[ |\delta I|/I_1 \leq 10^{-3}. \]

Figure 7: Fractional difference in the wakefield intensity for various fractional differences in the magnetic field \( \delta B / B_o \). The pump pulse has duration \( \tau_p = 500 \text{ psec} \), spot size \( 1 \text{ mm} \), and energy \( 100 \text{ mJ} \). The differences in magnetic field and corresponding intensities are from two nearby locations.

The pump pulse energy is \( I(\pi/2)R^2\tau_p \), where \( R \) is the spot size. For a pulse of duration \( \tau_p = 500 \text{ psec} \approx 2/\gamma_c \), \( R = 0.1 \text{ cm} \) and intensity \( I = 10^{10} \text{ W/cm}^2 \), the pump pulse energy is \( 80 \text{ mJ/pulse} \). For a pulse train, rep-rated at \( f_p = 1 \text{ kHz} \), the average pump laser power is \( \langle P \rangle = f_pI(\pi/2)R^2\tau_p = 80 \text{ W} \).
It is worth noting that at sufficiently high intensities, the upper level, level $|4\rangle$, can be populated resulting in a laser induced fluorescence signal to lower energy levels, i.e. levels $|1\rangle$ and $|3\rangle$. This process is known as the Hanle effect and is briefly discussed in Appendix C. The magnetization current resulting from the induced fluorescence of an $x$ polarized pump laser is $J_M \propto e^{-\gamma r} \cos(\omega r) \left[ \cos(\Omega r) \hat{e}_x - \sin(\Omega r) \hat{e}_y \right]$ [10]. Using polarization filters, the intensity on a detector due to the $x$ and $y$ components of the current density can be measured separately. Taking the ratio of the intensities from the $x$ and $y$ components of $J_M$ gives $I_x/I_y \propto \cot^2(\Omega_0 \tau)$. Note that the ratio is independent of the collision rate as long as the individual intensities are greater than the inherent intensity fluctuations.

V. Discussion and Concluding Remarks

Remote magnetometry has important applications, such as detection of underwater and underground objects. Detection of the magnetic anomaly caused by such an object is important to Navy missions. In the laboratory, under controlled environment, conventional magnetometry techniques can be used to measure extremely small magnetic field perturbations ($\sim \mu G$).

Limitations on remote detection include collisional dephasing of magnetic fluctuations, air turbulence, etc.

The paramagnetic species considered here is the oxygen molecule which has the magnetic dipole transition ($b^1\Sigma_g^+ - X^1\Sigma_g^-$) near 762 nm. We considered an intense pump laser to induce a polarization rotation of the wakefield. This transition is resonantly driven by a linearly-polarized pump laser pulse. Our examples suggest that the intensity of the rotated component of the wakefield can be measured.

Numerous issues remain to be considered, these include signal-to-noise ratio limitations, magnetic field orientation, pump laser absorption in the atmosphere, detection of the wakefield signal, possibility of inducing O$_2$ lasing.

Acknowledgement: We would like to acknowledge Dr. S. Potashnik for useful discussions. This work was supported by the Naval Research Laboratory Base Fund.
Appendix A. Transitions in Oxygen Molecule

Oxygen’s abundance in the earth’s atmosphere, approximately 21 % \( (N = 5.7 \times 10^{19} \text{ cm}^{-3}) \) and its paramagnetic response make it a possible candidate species for a remote optical magnetometer [4-7]. Molecular oxygen \( \text{O}_2 \) has two unpaired electrons in the upper level of the ground state, giving it a paramagnetic response. The ground state of oxygen \( \Sigma^+ \), commonly referred to as “triplet oxygen,” has total spin \( S = 1 \) and three degenerate sublevels. In atmospheric conditions near the surface of the earth (pressure \( P = 1 \text{ atm} \), total number density \( N_{\text{air}} = 2.7 \times 10^{19} \text{ cm}^{-3} \), and temperature \( T = 23.5 \text{ meV} \)), the ground state is fully populated because the next excited electronic state’s energy, \( E_a = 0.98 \text{ eV} \) is much greater than the thermal energy.

The electronic configuration of molecular oxygen is shown in Fig. 8. The first excited electronic state of oxygen, \( \Delta_g \), is referred to as “singlet oxygen” and only has one spin state \((S,m) = (0,0)\). This state has an energy of \( E_{a-X} = 0.98 \text{ eV} \), \( \Delta_g \) can undergo spontaneous emission via a magnetic dipole transition to the ground state \( \text{O}_2 \left( \Delta_g - \Sigma^+ \right) \) or \( a-X \). The \( a-X \) transition has a wavelength of 1.27 \( \mu \text{m} \). This transition is dominantly due to the orbital angular momentum \( L \) and has spontaneous emission rate of \( A_{a-X} = 2 \times 10^{-4} \text{ sec}^{-1} \) [14].

The second excited state of oxygen \( \Sigma^+ \) will be referred to as the upper state. It is also a spin singlet state with only one sublevel. The upper state can undergo three radiative transitions; \( \Sigma^+ - \Sigma^- (m = \pm 1) \), \( \Sigma^+ - \Sigma^- (m = 0) \) and \( \Sigma^+ - \Delta_g \) where the first and second transitions are between the different magnetic sublevels of the ground state and are referred to as the A band [11]. The transitions will be referred to as \( b-X,1, b-X,0 \), and \( b-a \) respectively. The \( b-X \) transitions have an energy of \( E_{b-X} = 1.63 \text{ eV} \), wavelength \( \lambda_{b-X} = 762 \text{ nm} \), and frequency \( \omega_{b-X} = 2.5 \times 10^{15} \text{ rad} \cdot \text{sec}^{-1} \). The calculated spontaneous emission rates of the \( b-X,1 \) and \( b-X,0 \) transitions are \( A_{b-X,1} = 0.087 \text{ sec}^{-1} \) and \( A_{b-X,0} = 1.6 \times 10^{-7} \text{ sec}^{-1} \) respectively [14].

The radiation from the \( b-X,1 \) transition can be seen in air-glow, night-glow and aurorae [14]. The \( b-X,1 \) transition is magnetic dipole- and spin-forbidden and it is dominant over the \( b-a \) and \( b-X,0 \) transitions which are electric quadrupole transitions [11]. This can be explained by a large spin-orbit coupling between the \( \Sigma^+ \) state and the \( \Sigma^- (m = 0) \) state. The spin-orbit coupling results in a mixing of the levels and the \( b-X,1 \). The \( b-a \) transition has an energy of \( E_{b-a} = 0.65 \text{ eV} \), wavelength \( \lambda_{b-a} = 1.9 \mu \text{m} \), frequency \( \omega_{b-a} = 9.9 \times 10^{14} \text{ rad} \cdot \text{sec}^{-1} \) and spontaneous emission rate of \( A_{b-a} = 1.4 \times 10^{-4} \text{ sec}^{-1} \) [14]. The transitions from the upper \( \Sigma^+ \) can be monitored by luminescence spectroscopy [14].
Figure 8: Electron occupancy energy levels of O₂ as two oxygen molecules are brought together.

**Appendix B. Density Matrix Equations**

Interaction of an oxygen molecule with radiation is governed by Schrödinger’s equation
\[ i\hbar \frac{\partial \psi}{\partial t} = H \psi \] where \( H = H_0 - \mu_m \cdot B(t) \) is the full Hamiltonian, \( H_0 \) is the electronic Hamiltonian after Zeeman splitting, and \( -\mu_m \cdot B(t) \) is the magnetic dipole interaction energy.

The wavefunction \( \psi(r, t) = \sum_n C_n(t) u_n(r) \) can be decomposed into the orthogonal energy eigenstates of O₂, \( u_n(r) \). The probability amplitudes \( C_n(t) \) are related to the density matrix elements \( \rho_{nm}(t) = C_n(t) C^*_m(t) \). The macroscopic electromagnetic fields are driven by a statistical ensemble of molecules, not a single molecule, and therefore it is necessary to use the density matrix equations and to introduce phenomenological relaxations terms, i.e.,

\[
\frac{\partial \rho_{nm}}{\partial t} = -i\omega_{nm} \rho_{nm} + i \sum_l \{ \Omega_{nl} \rho_{lm} - \Omega_{ln} \rho_{lm} \} + \text{relaxation terms}.
\]

In our model molecular oxygen is treated as a closed four level atom composed of the ground state \( O_2 \left( X^3\Sigma_g^- \right) \) and the upper level \( O_2 \left( b^1\Sigma_g^+ \right) \). The ground state has three spin sublevels \( m = -1, 0, +1 \) which are referred to as states \( |1\rangle \), \( |2\rangle \), and \( |3\rangle \) respectively. The excited upper level is referred to as state \( |4\rangle \). The complete set of coupled equations for the density matrix elements, assuming a closed system, are given by

\[
\frac{\partial \rho_{11}}{\partial t} = -\left( \Gamma_{12} + \Gamma_{13} \right) \rho_{11} + \Gamma_{21} \rho_{22} + \Gamma_{31} \rho_{33} + \Gamma_{41} \rho_{44} + i \left( \Omega_{14} \rho_{41} - \Omega_{41} \rho_{14} \right), \tag{B1}
\]

\[
\frac{\partial \rho_{22}}{\partial t} = \Gamma_{12} \rho_{11} - \left( \Gamma_{21} + \Gamma_{23} \right) \rho_{22} + \Gamma_{32} \rho_{33} + \Gamma_{42} \rho_{44}, \tag{B2}
\]
\[
\frac{\partial \rho_{33}}{\partial t} = \Gamma_{31} \rho_{11} + \Gamma_{23} \rho_{22} - \left( \Gamma_{31} + \Gamma_{32} \right) \rho_{33} + \Gamma_{43} \rho_{44} + i \left( \Omega_{34} \rho_{43} - \Omega_{43} \rho_{34} \right), \tag{B3}
\]
\[
\frac{\partial \rho_{44}}{\partial t} = -\left( \Gamma_{41} + \Gamma_{42} + \Gamma_{43} \right) \rho_{44} + i \left( \Omega_{41} \rho_{14} - \Omega_{14} \rho_{41} \right) + i \left( \Omega_{43} \rho_{34} - \Omega_{44} \rho_{43} \right), \tag{B4}
\]
\[
\frac{\partial \rho_{41}}{\partial t} = -\gamma_{41} \rho_{11} - i \omega_{41} \rho_{41} + i \Omega_{41} \left( \rho_{11} - \rho_{44} \right) + i \Omega_{43} \rho_{31}, \tag{B5}
\]
\[
\frac{\partial \rho_{43}}{\partial t} = -\gamma_{43} \rho_{33} - i \omega_{43} \rho_{43} + i \Omega_{43} \left( \rho_{33} - \rho_{44} \right) + i \Omega_{41} \rho_{13}, \tag{B6}
\]
\[
\frac{\partial \rho_{13}}{\partial t} = -\gamma_{13} \rho_{11} - i \omega_{13} \rho_{13} + i \Omega_{14} \rho_{14} - i \Omega_{43} \rho_{41}, \tag{B7}
\]

The population level of state \( |n \rangle \) is given by \( \rho_{nn} \) while the coherence between the states are given by \( \rho_{mn} = \rho_{nm}^* \). The transition frequencies are defined as \( \omega_{mn} = \omega_m - \omega_n \) where \( \hbar \omega_n \) is energy of the \( n^{th} \) state. For example, the state frequencies are \( \omega_1 = -\Omega_o \), \( \omega_2 = 0 \), \( \omega_3 = \Omega_o \), and \( \omega_4 = \omega_A \) and the transition frequencies are \( \omega_{41} = \omega_A + \Omega_o \), \( \omega_{13} = -2\Omega_o \), and \( \omega_{43} = \omega_A - \Omega_o \), where \( \omega_A = \Omega_b \left( \Sigma^+_g - X^3 \Sigma^-_g \right) \) is the Larmor frequency in the absence of a magnetic field. The Larmor frequency is given by \( \Omega_b = qB_o / (2mc) \) where \( q \) is the electric charge, \( B_o \) is the static background magnetic field, and \( m \) is the electron’s mass. Equations (B1)-(B7) imply conservation of population levels, i.e., \( \partial (\rho_{11} + \rho_{22} + \rho_{33} + \rho_{44}) / \partial t = 0 \) (closed system). The populations are additionally normalized unity, i.e. \( \text{Tr}(\rho) = 1 \). The interaction frequency between states \( m \) and state \( n \) is \( \Omega_{mn} = \Omega_{nm}^* \). Specifically, \( \hat{\Omega}_{43}(z,t) = \mu_m \hat{B}_L(z,t) / \hbar \) and \( \hat{\Omega}_{41}(z,t) = \mu_m \hat{B}_R(z,t) / \hbar \) where \( \mu_m \) is the effective magnetic dipole moment between triplet oxygen and the upper state and \( \hat{B}_R,L \) corresponds to is the right, handed polarization of the pump field. The rate equation for \( \rho_{42} \) is not considered since it does not couple to the those in Eqs.(B1)-(B7).

The rates \( \gamma_{41} \) and \( \gamma_{43} \) consist of contributions from i) elastic collisions (soft, dephasing collisions with no population transfers), ii) inelastic collisions (population transferring) and spontaneous emission. The elastic collision rate is taken to be the dominate rate and we set \( \gamma_{41} = \gamma_{43} = \gamma_{31} = \gamma_e \). In the absence of the pump field and at equilibrium we have \( \rho_{11} = \rho_{22} = \rho_{33} = \rho_o \) and \( \rho_{44} = 0 \). This implies that \( \Gamma_{21} = \Gamma_{12}, \Gamma_{31} = \Gamma_{13} \) and \( \Gamma_{23} = \Gamma_{32} \) and we take these rates, which include inelastic collisions and spontaneous emission, to equal \( \Gamma_o \). In addition, the rates \( \Gamma_{41}, \Gamma_{42} \) and \( \Gamma_{43} \) consist of inelastic collisions and spontaneous emission and we take these rates to be equal to \( \Gamma_u \). Taking the inelastic collision rates to be equal, i.e. \( \Gamma_o = \Gamma_u \), the density matrix equations become
\[
\dot{\rho}_{11}/\dot{t} = -\gamma_o (\rho_{11} - \rho^e_{11}) + i\left(\Omega_{14}\rho_{41} - \Omega_{41}\rho_{14}\right), \quad (B8)
\]

\[
\dot{\rho}_{22}/\dot{t} = -\gamma_o (\rho_{22} - \rho^e_{22}), \quad (B9)
\]

\[
\dot{\rho}_{33}/\dot{t} = -\gamma_o (\rho_{33} - \rho^e_{33}) + i\left(\Omega_{34}\rho_{43} - \Omega_{43}\rho_{34}\right), \quad (B10)
\]

\[
\dot{\rho}_{44}/\dot{t} = -\gamma_o (\rho_{44} - \rho^e_{44}) + i\left(\Omega_{41}\rho_{14} - \Omega_{14}\rho_{41}\right) + i\left(\Omega_{43}\rho_{34} - \Omega_{34}\rho_{43}\right), \quad (B11)
\]

\[
\dot{\rho}_{41}/\dot{t} = -\gamma_o \rho_{41} - i\omega_{41}\rho_{41} + i\Omega_{41}\left(\rho_{11} - \rho_{44}\right) + i\Omega_{43}\rho_{31}, \quad (B12)
\]

\[
\dot{\rho}_{43}/\dot{t} = -\gamma_o \rho_{43} - i\omega_{43}\rho_{43} + i\Omega_{43}\left(\rho_{33} - \rho_{44}\right) + i\Omega_{41}\rho_{13}, \quad (B13)
\]

\[
\dot{\rho}_{43}/\dot{t} = -\gamma_o \rho_{43} - i\omega_{43}\rho_{43} + i\Omega_{43}\left(\rho_{33} - \rho_{44}\right) + i\Omega_{41}\rho_{13}, \quad (B14)
\]

The phenomenological inelastic damping rate is given by \(\gamma_o = 3\Gamma_o = 3\Gamma_o U \approx 10^9 \text{sec}^{-1}\) [6]. The equilibrium populations for the ground state are \(\rho^e_{11} = \rho^e_{22} = \rho^e_{33} = 1/3\) and for the upper state \(\rho^e_{44} = 0\).

Appendix C. Resonant Fluorescent Excitation (Hanle effect)

At sufficiently high intensities laser induced fluorescence, i.e. Hanle effect, can be considered. The Hanle effect refers to the depolarization of resonant fluorescence lines by an external magnetic field [1,2,10]. It provides a sensitive experimental technique for a number of measurements, including remote measurement of planetary magnetic fields [15] and spontaneous emission rates [10], and spin depolarization rates [16]. It is also the basis of one of the most sensitive methods for measuring the lifetime of excited levels of atoms and molecules [17]. In the presence of a magnetic field the Zeeman sublevels of the ground state are split, resulting in a difference in the resonance frequencies for LHP and RHP light. The resulting phase difference between LHP and RHP light which is dependent on the ambient magnetic field, alters the polarization of fluorescing radiation.

To discuss this mechanism in more detail we consider a short intense laser pulse polarized in the x–direction \(E_{\text{pump}} = \hat{E}_o(\tau)e^{-i\omega\tau}(\hat{e}_x + \hat{e}_y) + \text{c.c.}\). This is just one of many orientations and configurations of the pump polarization and magnetic field direction in which the Hanle effect can occur.

The pump pulse is intense enough to excite level \(|4\rangle\) at the expense of levels \(|1\rangle\) and \(|3\rangle\). The pump pulse duration \(\tau_p\) is short compared to the collision time which in turn is short compared to a Larmor period. As the short duration, high-intensity polarized pump pulse sweeps
by it leaves behind an excited state which fluoresces with polarization components different than that of the pump. The fluorescence from the excited state $\rho_{44}$ to states $\rho_{11}$ and $\rho_{33}$ is described by the off-diagonal coherence of the molecular density matrix elements

$$\rho_{43} = -i\Omega_{RO} \tau_p \rho_{44} e^{-i(\omega_{43} - i\gamma_c)\tau} \quad \text{and} \quad \rho_{41} = -i\Omega_{LO} \tau_p \rho_{44} e^{-i(\omega_{41} - i\gamma_c)\tau},$$

where

$$\Omega_{RO} = -i\mu_m E_o / \hbar, \quad \Omega_{LO} = i\mu_m E_o / \hbar, \quad \omega_{43} = \omega - \Omega_o \quad \text{and} \quad \omega_{41} = \omega + \Omega_o.$$

The magnetization left behind the pump pulse is

$$M = -M_o e^{-\gamma_c \tau} (e^{-i\omega_{43} \tau} \hat{e}_r - e^{-i\omega_{41} \tau} \hat{e}_L) + \text{c.c.} \quad \text{where} \quad M_o = N \mu_m^2 (E_o / \hbar) \tau_p \rho_{44}.$$

The associated current density is

$$J_M = -M_o e^{-\gamma_c \tau} \left[ \omega_{43} \left\{ \cos(\omega_{43} \tau) - i \sin(\omega_{43} \tau) \right\} \hat{e}_R + \omega_{41} \left\{ \cos(\omega_{41} \tau) - i \sin(\omega_{41} \tau) \right\} \hat{e}_L \right] + \text{c.c.},$$

where

$$\omega_{43}, \omega_{41} \, \notin \, \gamma_c.$$ The current density has components in the x and y directions [10] which, for $\omega \, \notin \, \Omega_o$, are given by

$$J_M = -2M_o e^{-\gamma_c \tau} \omega \cos(\omega \tau) \left[ \cos(\Omega_o \tau) \hat{e}_x - \sin(\Omega_o \tau) \hat{e}_y \right].$$

(C1)

By using polarizer filters, the time average intensity on a detector due to the x and y components of the current density can be measured separately. Taking the ratio of the intensities from the x and y components of $J_M$ gives $I_x / I_y \propto \cot^2 (\Omega_o \tau)$. The ratio is independent of the collision rate as long as the individual intensities are greater than the inherent intensity fluctuations.
