Quantitative Comparison and Analysis of Species-Specific Wound Biofilm Virulence Using an In Vivo, Rabbit-Ear Model

Akhil K Seth, MD, Matthew R Geringer, BS, Robert D Galiano, MD, Kai P Leung, PhD, Thomas A Mustoe, MD, FACS, Seok J Hong, PhD

BACKGROUND: Although bacterial biofilm is recognized as an important contributor to chronic wound pathogenesis, differences in biofilm virulence between species have never been studied in vivo.

STUDY DESIGN: Dermal punch wounds in New Zealand white rabbit ears were inoculated with Klebsiella pneumoniae, Staphylococcus aureus, or Pseudomonas aeruginosa, or left uninfected as controls. In vivo biofilm was established and maintained using procedures from our previously published wound biofilm model. Virulence was assessed by measurement of histologic wound healing and host inflammatory mediators. Scanning electron microscopy (SEM) and bacterial counts verified biofilm viability. Extracellular polymeric substance (EPS)-deficient \textit{P}. aeruginosa was used for comparison.

RESULTS: SEM confirmed the presence of wound biofilm for each species. \textit{P}. aeruginosa biofilm-infected wounds showed significantly more healing impairment than uninfected, \textit{K}. pneumoniae, and \textit{S}. aureus (p < 0.05), while also triggering the largest host inflammatory response (p < 0.05). Extracellular polymeric substance-deficient \textit{P}. aeruginosa demonstrated a reduced impact on the same quantitative endpoints relative to its wild-type strain (p < 0.05).

CONCLUSIONS: Our novel analysis demonstrates that individual bacterial species possess distinct levels of biofilm virulence. Biofilm EPS may represent an integral part of their distinct pathogenicity. Rigorous examination of species-dependent differences in biofilm virulence is critical to developing specific therapeutics, while lending insight to the interactions within clinically relevant, polybacterial biofilms. (J Am Coll Surg 2012;215:388–399. © 2012 by the American College of Surgeons)

Bacterial biofilms, defined as a surface-adhered, complex community of aggregated bacteria within a matrix of extracellular polymeric substance (EPS), are increasingly being recognized as an integral component of chronic wound pathogenesis.\textsuperscript{1-7} Given the enormous burden that these wounds place on patients and the health care system,\textsuperscript{8-14} continued research aimed at delineating the mechanisms associated with wound biofilm development and maintenance remains critical. In particular, recent clinical studies have suggested that the predominant bacteria within a chronic wound can be one of several different species, and can often be present as polybacterial biofilm infections.\textsuperscript{2,4,7,15} These findings are supplemented by studies that have demonstrated the formation of biofilm by different bacterial species, including \textit{Staphylococcus aureus},\textsuperscript{16-18} \textit{Pseudomonas aeruginosa},\textsuperscript{19-21} and \textit{Staphylococcus epidermidis},\textsuperscript{22-24} in a variety of in vivo model systems. The potential for wound biofilms to originate from different, or multiple, bacterial species further complicates our limited understanding, indicating a need to examine biofilm pathophysiology at a species-specific level.

Biofilm-phase bacteria can be distinguished from their free-floating, “planktonic” counterparts by their inherent defense and survival mechanisms. The biofilm EPS provides a physical barrier against inflammatory cell phagocytosis, while also po-

have discovered and attributed a distinct level of virulence to each species. In line with clinical observation, we demonstrated that *P. aeruginosa* biofilm has the most significant effect on wound healing and the host inflammatory response. We investigated the mechanism of this pathogenicity using a mutant *P. aeruginosa* strain. In doing so, we implicated the EPS as a critical contributor to *Pseudomonas* virulence, which has not been previously reported. With these results, we also validate the sensitivity of our in vivo system, establishing the model as a valuable and informative tool for translational biofilm research.

**METHODS**

**Animals**

Under an approved protocol by the Animal Care and Use Committee at Northwestern University, adult New Zealand white rabbits (3 to 6 months old, approximately 3 to 4 kg) were acclimated to standard housing and fed ad libitum. All animals were housed in individual cages under constant temperature and humidity with a 12-hour light-dark cycle. A total of 26 rabbits were used to complete this study.

**Bacterial species**

Three separate bacterial species were used including individual strains of *K. pneumoniae* (BAMC 07-18), *S. aureus* (UAMS-1), and *P. aeruginosa* (PAO1 and mutant strain *pel*Δ*B*CD). The *K. pneumoniae* strain BAMC 07-18 (kindly provided by LTC Clinton Murray of Brooke Army Medical Center, Fort Sam Houston, TX) was originally isolated from the wounds of an injured soldier that had returned from Iraq during the war. PAO1 was obtained from the laboratory of Dr Barbara H Iglewski (University of Rochester Medical Center). *P. aeruginosa* mutant *pel*Δ*B*CD was kindly provided by Dr Tim Tolker-Nielsen of the University of Copenhagen. The *pel*Δ*B*CD mutant is a previously characterized double mutant of the *pel* and *psl* loci mutants, each of which causes deficiencies in the biosynthesis of polysaccharides that are part of *P. aeruginosa* EPS.

To prepare bacterial culture each species was grown on specific agar plates (Hardy Diagnostics; BAMC 07-18 on blood agar, UAMS-1 on *S. aureus* isolation agar, PAO1 and *pel*Δ*B*CD on *P. aeruginosa* isolation agar) overnight at 37°C. Each species was then subcultured at 37°C into 10 mL of tryptic soy broth (TSB; BAMC 07-18 and UAMS-1) or Luria broth (LB; *P. aeruginosa* strains) and grown at 37°C until log-phase was achieved. Bacteria were harvested and washed in phosphate-buffered saline (PBS) once by centrifugation at 5,000 rpm for 5 minutes at 20°C. The resultant pellet was resuspended in PBS and an optical density at the 600-nm wavelength (OD$_{600}$) was measured. For each species, an OD$_{600}$ equivalent to $10^6$ colony-forming units (CFU)/μL was determined pre-empirically.
Wound protocol and infection model

Rabbits were anesthetized with intramuscular injection of a ketamine (22.5 mg/kg) and xylazine (3.5 mg/kg) mixture before surgery. Ears were shaved, sterilized with 70% ethanol, and injected intradermally with 1% lidocaine/1:100,000 epinephrine at the planned wound sites. Six, 6-mm diameter, full-thickness dermal wounds were created on the ventral side of each ear, totaling 12 wounds per rabbit, down to perichondrium and dressed with Tegaderm (3M Health Care), a semiocclusive transparent film. Individual wounds were either left sterile as uninfected controls or inoculated with 10⁶ CFU of an individual test bacteria strain on postoperative day (POD) 3. Each rabbit was designated as a control or was infected with only bacterial species, with no cross-contamination of bacteria within or between ears. For each study group, 60 wounds (5 rabbits) were used for data analysis, totaling 300 wounds (25 rabbits; Table 1). Because we had no previous experience using the P aeruginosa mutant strain pelApslBCD, an additional animal was inoculated with pelApslBCD to ensure feasibility and animal safety, but was not included in any analyses.

Bacteria were allowed to proliferate under the Tegaderm dressing. Topical Mupirocin (2%; Teva Pharmaceuticals) or Ciloxan (Ciprofloxacin 0.3%, Alcon) antibiotic ointment was applied on postoperative day (POD) 4 to S aureus and K pneumoniae or P aeruginosa infected wounds, respectively, to eliminate free-floating, planktonic-phase bacteria, leaving a predominately biofilm-phase phenotype. To prevent seroma formation and regrowth of planktonic bacteria, therefore maintaining a biofilm-dominant infection, an antimicrobial, absorbent dressing containing polyhexamethylene biguanide (Telfa AMD, Tyco Healthcare Group) was applied to biofilm wounds on PODs 5 and 6, and then every other day until harvest. An overlying Tegaderm dressing was maintained throughout the protocol, and all dressings were checked daily.

Harvesting of wounds

After euthanizing animals by intracardiac euthasol injection, wounds were harvested for various analyses at different time points. Wounds for histologic analysis using hematoxylin and eosin (H&E) staining, and scanning electron microscopy (SEM) to visualize biofilm morphology, were harvested at POD 12. For quantitative reverse transcription-polymerase chain reaction (qRT-PCR) analysis to measure inflammatory cytokine mRNA levels, and viable bacterial counts, wounds were harvested on POD 6. For each analysis endpoint, wounds were taken from both ears from multiple animals (eg, qRT-PCR: 3 wounds from the left ear and 3 wounds from the right ear from rabbits 1 and 2; Table 1) to account for any potential inherent variability between rabbits. All wounds were excised using a 10-mm (histology, SEM, viable bacterial counts) or 7-mm (qRT-PCR) biopsy punch (Acuderm Inc). Wounds were omitted from the final results if difficulties were encountered during tissue handling or processing that prevented appropriate or consistent analysis.

Histologic analysis

Wounds excised for histologic analysis were bisected at their largest diameter for hematoxylin and eosin staining. Tissues were fixed in formalin, embedded in paraffin, and cut into 4-μm sections. Paraffin was removed with a xylene wash, followed by a standard hematoxylin and eosin staining protocol to prepare samples for analysis under a light microscope. Slides were examined for quantification of epithelial and granulation gaps, and total granulation area, using a digital analysis system (NIS-Elements Basic Research, Nikon Instech Co), as previously described. In brief, epithelial and granulation gaps were measured as the distance between the distal leading edges of any newly formed epithelial and granulation tissue, respectively. New granulation tissue area was defined as the sum of the granulation tissue in-growth areas on either side of the wound, inside of the 6-mm wound border. The wound border was determined histologically by the “nick” in the cartilage on either side of the wound bed and/or visual differences in the

tissue between existing dermis and newly formed granulation tissue. Two blinded, independent observers evaluated all histologic sections. The results of both examiners were averaged. Slides were omitted if results differed more than 30% among examiners.

**Scanning electron microscopy**

To determine biofilm structure, wound samples were fixed in 2.5% glutaraldehyde in 0.1 M (pH 7.2), washed 3 times in PBS, and dehydrated through an ethanol series and hexamethyldisilazane. Samples were mounted by double-sided tape to specimen stubs, followed by gold-platinum (50:50) ion coating (108 Auto Sputter Coater, TedPella, Inc). Wounds for SEM had their dorsal sides removed before preparation to allow for better mounting for visualization. Samples were visualized using a Carl Zeiss EVO-40 scanning electron microscope operated at the scanning voltage of 10 kV. Sterile control wounds were used as a baseline for visual comparison against infected wounds.

**Total mRNA extraction and quantitative reverse-transcription polymerase chain reaction**

The dermal layer on the dorsal side of the ear was removed for wounds harvested for mRNA extraction and subsequent cDNA conversion as part of qRT-PCR. Wounds were excised using a 7-mm punch, with an original 6-mm wound bed, leaving a 0.5-mm diameter rim of normal skin around the wound bed. Based on previous work with this model,16 harvest for mRNA extraction was done on POD 6. At this time, a steady-state of biofilm-phase bacteria is thought to be present after topical antibiotic and Telfa dressing placement, triggering the largest inflammatory response. Wounds were immediately snap-frozen in liquid nitrogen after excision. Before mRNA extraction, wound samples were homogenized using a Mini-bead beater-8 (Biospec Products Inc) with zirconia beads (2.0 mm diameter). One mL of PBS was added and the tube was homogenized for 90 seconds at 5,000 rpm in a MagnaLYSER homogenizer (Roche) and then sonicated (Microson Ultrasonic Cell Disrupter, Heat Systems-Ultrasonics, Inc) for 2 minutes at 6 to 8 watts to disrupt biofilms and release any bacteria present within the structures.

For quantitative analysis of the level of mRNAs, qPCR analyses using SYBR green 1 were performed using an ABI prism 7000 sequence detection system (Applied Biosystems). Polymerase chain reaction primers were designed using the Primer 3 program (http://frodo.wi.mit.edu/). Expression of each gene was normalized to the level of glyceraldehyde 3-phosphate dehydrogenase (Gapdh), the housekeeping gene, to get ∆∆Ct. The 2^(-∆∆Ct) method was used to calculate mRNA levels of interleukin (IL)-1β and tumor necrosis factor (TNF)-α within the wounds of interest. Expression of genes was detected by PCR with the following oligonucleotides: IL-1β (forward: 5’-CCACAGTGCGAATGAAAATG-3’ and reverse: 5’-AGAAAGTTCTCAGGCG-GTCA-3’, accession D21835), TNF-α (forward: 5’-CCAGATGTCACCCCTACAGAT-3’ and reverse: 5’-TGT-TCTGAGAGCCGTGATG-3’, accession NM_001082253). Values were then further normalized by expressing the mRNA level as a fold-difference over the level seen in nonwounded skin. Nonwounded skin was obtained from ears of control animals designated for qRT-PCR.

**Viable bacterial counts**

The dorsal side of wounds used for bacterial counts were removed to eliminate the inclusion of bacteria outside of the infected wound surface. These wounds were harvested on POD 6 to correlate the qRT-PCR results with the extent of bacterial burden seen in each wound. To recover bacteria, infected wound samples were placed in tubes prefilled with homogenizer beads (Roche). One mL of PBS was added and the tube was homogenized for 90 seconds at 5,000 rpm in a MarnaLYSER homogenizer (Roche) and then sonicated (Microson Ultrasonic Cell Disrupter, Heat Systems-Ultrasonics, Inc) for 2 minutes at 6 to 8 watts to disrupt biofilms and release any bacteria present within the structures. For each bacterial species, the resulting solutions were serially diluted and plated on the appropriate agar plates, as used during bacterial culturing. Plates were incubated overnight at 37°C. Colony forming units were determined by standard colony counting method. Control wounds designated for “bacterial counts” were plated to ensure baseline sterility of wounds relative to those inoculated with a specific bacteria.

**Statistical analysis**

Data are presented in graphic form as mean ± standard errors when applicable. Statistical analyses were performed using the Student’s t-test (2-tailed, unpaired) when comparing 2 study groups, and 1-way analysis of variance (ANOVA) when comparing the means of multiple groups. The level of significance was set at p < 0.05.

**RESULTS**

To validate the presence of biofilm-phase bacteria within our wounds, SEM imaging was performed for each bacterial species (Fig. 1). In each case, wounds revealed the presence of the inoculated bacteria throughout the wound bed.
K pneumoniae wounds demonstrated characteristic rod-shaped bacteria with some cells in clusters, typical of biofilm morphology (Fig. 1A). Similar patterns were verified with the cocci-shaped S aureus (Fig. 1B) and rod-shaped P aeruginosa (Fig. 1C) wounds. However, P aeruginosa wounds tended to possess a higher density of EPS material as compared with K pneumoniae and S aureus. This EPS appeared organized into a well-defined matrix and interspersed within clusters of P aeruginosa cells.

Having verified the consistency of our in vivo model to form biofilm across multiple bacterial species, an analysis of each species’ effects on wound healing was performed. Gross appearance of biofilm-infected wounds revealed distinct differences in wound healing at POD 12 (Figs. 2A to 2C). In particular, P aeruginosa wounds demonstrated an overall greater impairment in healing as compared with both S aureus and K pneumoniae. Notable differences also existed between S aureus and K pneumoniae, with K pneumoniae consistently having the largest amount of healing. This hierarchy of wound healing inhibition between species was further supported by histologic analysis (Figs. 2D to 2F). K pneumoniae wounds appeared to have the largest amount of epithelial and granulation tissue among the 3 species (Fig. 2D); P aeruginosa imparted the greatest inhibitory effect over the same time period (Fig. 2F). Quantification of these histologic parameters revealed statistically significant differences between P aeruginosa biofilm-infected wounds and uninfected, K pneumoniae, and S aureus wounds in both wound epithelialization and granulation (p < 0.05; Fig. 3). Furthermore, the incremental progression in virulence was maintained when averaged across multiple wounds (n = 16 to 20 wounds/species), progressing from K pneumoniae to S aureus to P aeruginosa.

Individual bacteria species’ virulence was further assessed through measurement of the extent of host inflammatory response to each species. The mRNA levels of inflammatory cytokines IL-1β and TNF-α were measured through qRT-PCR for each species, followed by normalization to the level seen in nonwounded skin (Figs. 4A, 4B). For both cytokines, P aeruginosa demonstrated significantly higher levels of mRNA as compared with the other 2 species (p < 0.05), indicating a relatively heightened inflammatory response to the presence of P aeruginosa biofilm within wounds. Viable bacterial counts were then performed at the same time point to ensure that differences in the host response were not related to measurable differences in bacterial burden (Fig. 4C). There were no differences in viable bacteria levels between K pneumoniae and S aureus. However, P aeruginosa wounds had significantly lower viable bacteria counts (p < 0.01) across all wounds (n = 8 to 10 wounds/species) than K pneumoniae or

**Figure 1.** Scanning electron microscopy images of wound biofilms from each bacterial species studied. (A) K pneumoniae and (B) S aureus wounds revealed clustering of rod- and cocci-shaped bacterial cells, respectively, on the wound surface with minimal amounts of extracellular polymeric substance (EPS) matrix components between cells. (C) P aeruginosa wounds demonstrated smaller numbers of cells with large amounts of lattice-like EPS matrix (arrows) interspersed between bacteria.
S aureus, despite triggering the largest inflammatory response among all 3 species.

The impressive virulence of P aeruginosa, relative to K pneumoniae and S aureus, prompted further investigation into the potential mechanism(s) contributing to these differences. Given the density of EPS in P aeruginosa wounds relative to the other 2 species studied, further experiments were performed using the P aeruginosa EPS-deficient mutant pelApslBCD to investigate EPS’ potential role in P aeruginosa virulence. Scanning electron microscopy of wounds infected with the pelApslBCD mutant bacteria verified the expression of an EPS-deficient phenotype, with a distinct lack of polymeric substance components between bacterial cells as compared with the PAO1 wild-type strain (Fig. 5). However, despite the deficiency in EPS, pelApslBCD mutants did demonstrate some bacterial clustering, as would be expected by biofilm-phase bacteria (Figs. 5C, 5D).

Differences in virulence between wild-type PAO1 and the EPS-deficient mutant pelApslBCD were assessed using the endpoints previously described for comparing K pneumoniae and S aureus with P aeruginosa. The gross appearance of pelApslBCD-infected wounds revealed improved healing relative to PAO1-infected wounds (Figs. 6A, 6B). This result was also seen on histologic comparison, with visual (Figs. 6C, 6D) and quantitative (Fig. 7) differences in the extent of wound healing inhibition between the wild-type and mutant strains of P aeruginosa. Measurement of inflammatory cytokine mRNA levels corroborated these differences in virulence, with a significantly lower host response to the presence of the pelApslBCD mutant in the wound (p < 0.05; Figs. 8A, 8B). The number of viable bacteria in pelApslBCD-infected wounds was equivalent to that of PAO1 wounds (Fig. 8C), indicating that the differences in inflammatory cytokine expression were inherent to the bacterial strains themselves.

DISCUSSION

Understanding bacterial biofilm pathogenicity remains essential to developing effective treatment strategies for chronic wounds. With several resistance mechanisms and its dynamic response to environmental cues such as in wounds, the ability of biofilm to originate from one of several different bacterial species only increases its complexity. Although many principles of biofilm dynamics are conserved across bacterial species, potential differences in biofilm virulence between species have not been studied. Using an established, in vivo wound biofilm model, we investigated and compared the virulence of different, species-specific, bacterial biofilms by quantifying their effects on wound healing and the host inflammatory response. As a result, we have used our findings to highlight a previously underappreciated contributor to biofilm pathogenicity.

The current literature surrounding biofilm pathogenicity and virulence has focused on a variety of molecular pathways and bacterial species. In S aureus, many groups have focused on the accessory regulator protein sarA as a key mediator of biofilm formation. Beenken and colleagues demonstrated that mutation of sarA limited the development of S aureus biofilm in vitro, while the addition of a mutation in another accessory gene regulator, agr, did not incrementally effect the end phenotype. More recently, Weiss and associates demonstrated that in a catheter-
associated in vitro biofilm model, mutation of sarA resulted in an increased susceptibility of in vitro biofilm to antibiotics. Meanwhile, a number of groups have continued to demonstrate the importance of quorum-sensing to *P. aeruginosa* virulence,21,30,40 although work from Schaber and coworkers41 indicates that even quorum-sensing deficient *P. aeruginosa* are capable of forming in vivo biofilms in a thermally injured mouse model. Nevertheless, the virulence of different bacterial species has never been directly compared, making it difficult to extrapolate these findings to polybacterial settings. In addition, as previously mentioned, there re-

Figure 3. Comparison of quantitative histologic parameters between the 3 bacterial species studied. Measurements of (A) epithelial and (B) granulation gaps and (C) new tissue granulation area revealed that *P. aeruginosa* wounds had significantly impaired healing compared with uninfected controls (***p < 0.001), *K. pneumoniae* (***p < 0.001), and *S. aureus* (*p < 0.05) across all measured histologic parameters (n = 16 to 20 wounds/species).

Figure 4. Comparison of inflammatory cytokine mRNA levels and viable bacterial counts in biofilm-infected wounds. *P. aeruginosa* wounds at postoperative day (POD) 6 demonstrated significantly higher levels of mRNA for inflammatory cytokines (A) interleukin (IL)-1β and (B) tumor necrosis factor (TNF)-α as compared with *K. pneumoniae* and *S. aureus* wounds (***p < 0.001; n = 8 to 10 wounds/species). (C) Bacterial counts were performed at POD 6 to ensure differences in inflammatory cytokine mRNA levels were not related to large differences in wound bacterial burden. *K. pneumoniae* and *S. aureus* biofilm-infected wounds revealed similar levels of bacterial counts. However, despite triggering a greater host inflammatory response, *P. aeruginosa* biofilm-infected wounds demonstrated significantly lower levels of viable bacteria relative to the other 2 species (***p < 0.001; n = 8 to 10 wounds/group).
mains little evidence to support the importance of the EPS to biofilm virulence. Early work by Deighton and colleagues suggested that the extracellular “slime” of *S. epidermidis* biofilm-based catheter infections delayed the clearance of *S. epidermis* relative to biofilm-negative strains. In 2010, Borlee and associates reported on an adhesin molecule important to the structural integrity of *P. aeruginosa* EPS, but did not extend these findings to its effect on

![Figure 5](image1.png)

**Figure 5.** Scanning electron microscopy of *P. aeruginosa* wild-type (PAO1) and mutant (*pelApsIBCD*) biofilm-infected wounds. Wild-type wounds (A and B) revealed large amounts of extracellular polymeric substance (EPS) matrix arranged in a lattice-like structure (arrows). In contrast, EPS-deficient mutant *pelApsIBCD* wounds (C and D) demonstrated minimal amounts of matrix between individual bacterial cells despite some evidence of clustering (arrows). The lack of EPS in *pelApsIBCD* wounds verified the phenotype that was expected morphologically.

![Figure 6](image2.png)

**Figure 6.** Gross appearance and histologic sections of (A and C) wild-type PAO1- and (B and D) mutant *pelApsIBCD*-infected wounds on postoperative (POD) 12 before harvest. (B) Wounds infected with *pelApsIBCD* appeared to have consistently smaller gaps in epithelial and granulation tissue compared with (A) PAO1, indicating a decreased ability to impair wound healing. Histologic sections stained with hematoxylin and eosin at POD 12 showed that (D) mutant *pelApsIBCD* wounds had improved healing compared with (C) PAO1 wounds, including a smaller epithelial gap, correlating with their gross appearance. (Magnification × 20) EG, epithelial gap.
P aeruginosa virulence. Consequently, there remains limited evidence on the importance of the EPS to biofilm pathogenicity, particularly in vivo.

Through this study, we have demonstrated measurable differences in biofilm virulence between K pneumoniae, S aureus, and P aeruginosa. An analysis of their effects on wound healing inhibition and the host inflammatory response revealed that P aeruginosa biofilm was the most pathogenic species studied. In particular, P aeruginosa had the greatest effect on inflammatory cytokine expression despite the smallest number of viable bacteria. However,
visualization of biofilm morphology on SEM showed that \textit{P aeruginosa} had the highest density of EPS among the 3 species, prompting additional investigation using an EPS-deficient \textit{P aeruginosa} mutant. By observing a significant decrease in virulence from wild-type to mutant \textit{P aeruginosa}, we concluded that the EPS is a critical factor in the heightened virulence of \textit{P aeruginosa}.

Although several biofilm virulence factors have been identified for different bacterial species, no studies have performed a direct comparison of species-specific virulence using multiple endpoints. Through quantification of these differences, we have established a hierarchy of biofilm virulence among these common pathogens. These findings have multiple clinical implications for biofilm-infected chronic wounds. Previous work from our group has demonstrated that frequent, aggressive, and multimodal clinical wound care against \textit{P aeruginosa} biofilm is necessary to obtain significant improvements in wound healing and bacterial viability.\textsuperscript{35} However, wounds infected with a less virulent bacterial species, such as \textit{K pneumoniae}, may not require the same level of treatment. Differentiating the severity of chronic wound infections based on the infecting bacteria’s virulence can help with the development of appropriate treatment plans, while also allowing for prioritization of wound care resources. In addition, given that most chronic wounds are infected by multiple bacteria species,\textsuperscript{2,4,7,15} understanding the contribution of each bacterial species to the overall infection is important for developing effective therapeutics against a polybacterial biofilm. These differences in virulence may also have an impact on the dynamics of a polybacterial infection by influencing the interactions that occur between bacterial species.

It is particularly notable that \textit{K pneumoniae} was found to have the least virulent wound biofilm among species studied, given its pathogenicity in other organ systems.\textsuperscript{44} Although not a common chronic wound pathogen, relative to \textit{S aureus} and \textit{P aeruginosa}, multidrug resistant strains of \textit{K pneumoniae} have been identified in the infected wounds of soldiers returning from war in Iraq.\textsuperscript{45} Despite the tissue damage seen in these wounds, our results using one of these clinically isolated strains indicate that these strains may trigger only a modest amount of healing impairment when in a monospecies infection. Therefore, one can speculate that the detrimental effects of \textit{K pneumoniae} wound biofilm may actually be potentiated in a polymicrobial environment, such as that within an infected war wound. However, additional work is needed to understand these dynamic differences in the pathogenicity of a single bacterial species.

The high level of virulence exhibited by \textit{P aeruginosa} was investigated through the use of an EPS-deficient mutant strain of \textit{P aeruginosa}. Recent literature has focused on quorum-sensing between \textit{P aeruginosa} cells as a critical virulence factor,\textsuperscript{2,21,29,30} with the goal of developing therapeutics aimed at disrupting these cell-to-cell signaling pathways. However, there is little evidence to date that \textit{P aeruginosa} EPS may also be an important mediator of its biofilm pathogenicity. Qin and coworkers\textsuperscript{46} used the same mutant, \textit{pelApslBCD}, to demonstrate that extracellular products within the supernatant of \textit{P aeruginosa} are capable of disrupting \textit{S. epidermidis} biofilm formation in vitro. Meanwhile Koo and associates\textsuperscript{47} suggest that in oral biofilms, the EPS of \textit{S mutans} can contribute to the pathogenesis of dental caries. In similar fashion, our results indicate that \textit{P aeruginosa} deficient in EPS triggers a milder inflammatory response and a decreased impairment in wound healing when compared with wild-type. As previously discussed, the EPS provides a number of protective advantages against host defense mechanisms,\textsuperscript{22,25-28} which may provide an explanation for our findings. However, EPS consists of a diverse group of polymers, including polysaccharides, proteins, and nucleic acids.\textsuperscript{48} This complexity indicates that it may act as a platform for dynamic signaling pathways rather than being solely a physical barrier. Furthermore, the high density of EPS seen in \textit{P aeruginosa} biofilms on SEM, as compared with \textit{K pneumoniae} and \textit{S aureus}, may further validate its contribution to the differences in virulence that we report. However, given that each species produces its own specific EPS using different substrates, it is difficult to validate this relationship without further molecular studies.

**CONCLUSIONS**

The potential importance of the EPS to biofilm virulence indicates a need for further investigation into therapeutics aimed at disrupting its dense structure. Traditional wound care methods, such as debridement and lavage, have been shown to disturb \textit{P aeruginosa} biofilm structure in previous iterations of our model.\textsuperscript{43} However, without an aggressive regimen of frequent multimodality treatments, the biofilm EPS appears to regain its structure, and therefore presumably some of its virulence as well. Others have demonstrated that topical formulations of specific D-amino acids are effective in both preventing biofilm growth and triggering disassembly of biofilm structure in both \textit{S aureus} and \textit{P aeruginosa}.\textsuperscript{48,49} Treatments such as these not only weaken the physical barrier that the EPS provides, but may also reduce the effectiveness of any innate virulence factors that it may have. Although biofilm research continues to focus on mechanisms of virulence such as quorum sensing, we believe our findings highlight the importance of a renewed interest in understanding, and targeting, the molecular pathways associated with biofilm EPS.
We acknowledge that despite our novel findings, our study is limited by a lack of understanding of species-specific biofilm virulence at a molecular level. Instead, we have performed work that has outlined the dynamics of different species’ biofilms, while preliminarily implicating the EPS as a potential target warranting future investigation. However, we chose to not expand our initial investigation of EPS to *S. aureus and K. pneumoniae* given the ready availability of an EPS-deficient *P. aeruginosa* mutant. Understanding the individual role of EPS in different species of bacteria will be crucial in implicating it as a therapeutic target. Furthermore, we did not perform additional experiments to compare the importance of EPS to other virulence factors, such as the well-known quorum-sensing pathways of *P. aeruginosa*. However, with the power of this in vivo model, we have created a solid foundation for being able to compare different virulence factors whose end effects might otherwise be difficult to differentiate from one another. As our understanding of biofilm virulence continues to grow, our ability to counteract its destructive effects on chronic wounds will also improve. Future studies extending from this work will help further define the relationships and mechanisms introduced here, setting the stage for a new era of microbiologic therapeutics.
