December 1994

The SACLANT Undersea Research Centre provides the Supreme Allied Commander Atlantic (SACLANT) with scientific and technical assistance under the terms of its NATO charter, which entered into force on 1 February 1963. Without prejudice to this main task – and under the policy direction of SACLANT – the Centre also renders scientific and technical assistance to the individual NATO nations.
This document is released to a NATO Government at the direction of SACLANT Undersea Research Centre subject to the following conditions:

- The recipient NATO Government agrees to use its best endeavours to ensure that the information herein disclosed, whether or not it bears a security classification, is not dealt with in any manner (a) contrary to the intent of the provisions of the Charter of the Centre, or (b) prejudicial to the rights of the owner thereof to obtain patent, copyright, or other like statutory protection therefor.

- If the technical information was originally released to the Centre by a NATO Government subject to restrictions clearly marked on this document the recipient NATO Government agrees to use its best endeavours to abide by the terms of the restrictions so imposed by the releasing Government.

Inversion for geometric and geoacoustic parameters in shallow water:

Experimental results

D.F. Gingras and P. Gerstoft

Executive Summary: The localization of targets in the underwater environment is of vital interest for both passive and active sonar applications. The use of full field inversion methods or ‘matched-field’ processing for target localization has been shown to be effective for determining target bearing, range and depth. The performance of these methods is strongly dependent on the accuracy of the knowledge about the environmental parameters. Previously the lack of precise knowledge about the environmental parameters inhibited the application of these methods in shallow water. The objective of this report is to demonstrate that target location parameters and environmental parameters can be jointly estimated. The results are based on sea trial data collected by SACLANTCEN in October 1993 in the Mediterranean.

This report focuses on the estimation of target location parameters using global estimation methods as a preprocessor for estimation of the environmental parameters. Since the target location and parameters cannot be decoupled, global estimation methods were first used to jointly estimate both types of parameters. Then the forward model parameters were used in a standard matched-field processor for target localization. The use of the global estimates significantly improved source localization results as compared to those obtained without the estimated model parameters. This report provides successful results on the estimation of both geometric and geoacoustic parameters using global optimization methods with real data in shallow water.

To date these target localization methods have been applied to passive sonars, in the future it is expected that they will also be applied to active sonars.
Inversion for geometric and geoacoustic parameters in shallow water:

Experimental results

D.F. Gingras and P. Gerstoft

Abstract: Experimental results on the estimation of both geometric and geoacoustic parameters in shallow water are presented. Genetic algorithms are used for estimation of the forward model parameters, the estimated parameters are then used by a standard Bartlett processor for source localization. A stationary source at a range of 5.6 km and a moving source at ranges from 5.8 to 7.7 km were successfully localized in range and depth using a single frequency Bartlett processor. It is demonstrated that global estimation of the forward model parameters significantly improved source localization performance.

Keywords: detection ◦ estimation ◦ genetic algorithms ◦ shallow water
Acknowledgements: The authors wish to acknowledge the significant contribution of the SACLANTCEN Electronic-Acoustic Engineering and Ocean Engineering Departments for their diligent preparation and operation of the sea-going equipment and the captain and crew of the R/V Alliance for their outstanding contributions to the sea-going operations. The support of the Italian Navy, in particular the crew of the ITN Palmaria, is also appreciated.
The inversion of acoustic field data using the 'matched-field' processing method is a widely accepted procedure for estimating both geometric and geoacoustic parameters. The so-called 'matched-field' method simply implies that acoustic field observations are 'matched' in some sense to multiple iterations of a forward model as a function of search parameters. This form of processing has been applied to a variety of estimation problems including source localization, see for example [1-7], tomography [8], and inversion for ocean and ocean bottom properties [9-13]. In many cases the 'matching' is accomplished via a correlation process often referred to as the linear or Bartlett processor.

In general there is no direct solution for the estimation of ocean and bottom parameters from acoustic field observations. Often this inverse problem is posed as a nonlinear optimization problem. The problem is formulated by assuming a discrete forward model parameter vector \( \mathbf{m} = \{ m_i \} \) of unknown parameters with a bounded range of possible values for each parameter. An object function which provides a measure of the similarity between the observed field and the field predicted via forward modeling is optimized with respect to the model vector. In most situations the model parameter search space is extremely large, thus solution via exhaustive search is not a viable option. Furthermore, the object function may contain many local minima precluding the use of gradient decent methods. Efficient global optimization methods such as simulated annealing (SA) and genetic algorithms (GA) must be employed [9-13].

Collins and Kuperman were the first to include the 'environmental' parameters into the search space for source localization [9]. Simulation results were presented which demonstrated the utility of using SA to search the expanded search space. In Ref. [10] SA was applied to the estimation of ocean-bottom properties, successful results were obtained using real data. References [11,12] provided results based on simulations for the estimation of ocean-bottom properties using SA. The first application of GA methods to the estimation of geoacoustic parameters was by Gerstoft [13], where successful results were obtained using synthetic data.

There have been a number of papers reporting on experimental results for the estimation of source location parameters in shallow water using matched-field processing. In 1989, Hinich and Sullivan [2] reported a localization based on a mode filtered maximum likelihood method. Only a single localization was reported and for this case the depth estimate was not correct. They reported that the lack of results was perhaps due to array motion. Ozard [3] reported on a localization involving
a short horizontal array. There were no reliable range estimates reported but the depth estimation results were encouraging. Hamson and Heitmeyer [4] reported on source localizations in shallow water. In this case three successful localizations were reported, all at different frequencies. In all three cases the sidelobe level was very close to that of the source peak. In 1990, Feuillade et al. [5] reported a single shallow water localization in very shallow water (33 m) using the Capon maximum likelihood processor. In 1993, Jesus [6] reported on successful source localizations for transient signals. Reasonably accurate estimates for both range and depth were reported. The results of Ref. [6] were the only shallow water results that reported consistent range and depth estimates over time. In all of the above, the geoacoustic parameters were assumed to be known and were not estimated as part of the localization process.

In October 1993 SACLANTCEN conducted a sea trial in the Mediterranean Sea using a vertical array in shallow water. The trial was conducted in an area where the geoacoustic properties were reasonably well known from previous SACLANTCEN experiments [14–16]. An objective of the October 1993 experiment was to verify the performance of field inversion methods in shallow water under somewhat optimal conditions, i.e., an array that spanned most of the water column, knowledge of hydrophone positions via array positioning, a stationary and moving source, and a priori knowledge of the geoacoustic parameters.

This report focuses on the estimation of source location parameters using global estimation methods as a preprocessor for estimation of the other forward model parameters. Since the geometric and geoacoustic parameters cannot be decoupled global estimation methods were first used to jointly estimate both types of parameters. Then the forward model parameters were used in a standard matched-field processor for source localization. The use of the global estimates significantly improved source localization results as compared to those obtained without the estimated model parameters. This report provides successful results on the estimation of both geometric and geoacoustic parameters using global optimization methods with real data in shallow water.

In Sect. 2 a brief summary of the trial site and equipment deployed is provided. In Sect. 3 a brief overview of GA is presented along with the results obtained for the geometric and geoacoustic parameter inversion. In Sects. 4 and 5 the source localization results, based on the estimated forward model parameters, are presented for a stationary and moving source. Finally in Sect. 6 a discussion of the results is presented.
Experimental setup

The experimental data were collected over a two-day period on 26 and 27 October 1993 in a shallow water area north of the island of Elba, off the west coast of Italy, where environmental conditions were known from earlier SACLANTCEN experiments [14-16]. This area is characterized by a flat bottom covered with clay and sand-clay sediments. The trial was conducted in a flat area between the 120 m and 140 m depth contours along a track running parallel to the depth contours. The propagation conditions were typical downward refracting summer conditions. The weather over the two day period was favorable, a sea-state of 2 to 3, the wind on the 26th was variable between 6 and 10 m/s and on the 27th it averaged about 3 m/s.

On the morning of the 26th the vertical array, array positioning transponders, and a stationary source buoy were deployed. On the afternoon of the 27th a support ship, the ITN Palmaria, provided a moving source along the track indicated by points A and B on Fig. 1. Figure 1 also indicates the relative locations for the vertical array and the source buoy along with the local bathymetry. Acoustic field data from the two sources, array positioning data, sound-speed profile and current vs depth profile data were acquired over the two-day period.

![Figure 1](image-url)  
**Figure 1** Bathymetry, equipment locations and ship track.
2.1. VERTICAL ARRAY AND ARRAY POSITIONING

The vertical array was deployed at 43°02.86'N 10°10.01'E. Due to the accuracy of the GPS system on board R/V Alliance the position of the vertical array is only known within ±100 m. The bathymetry was measured to be approximately 127 m at the array site. The vertical array was deployed in a bottom-moored configuration with ballast and a sub-surface low-drag float, see Fig. 2. The multi-channel array hydrophone data was digitized in the array, transmitted via a cable to a surface buoy and then transmitted via a radio link to the real-time processing and archival storage system on board the R/V Alliance. The vertical array had a total aperture of 94 m; within the 94 m aperture a total of 48 hydrophones with 2 m spacing were used. Based on the physical configuration shown in Fig. 2 and the measured bathymetry of 127 m at the array site the bottom hydrophone was at a depth of 112.7 m. The hydrophone closest to the surface was correspondingly at a depth of 18.7 m. These are nominal depths based on the above assumptions, the actual depths were different due to array tilt, imprecise measurement of the bathymetry and ballast penetration into the sediment.

In order to determine the variation of the array hydrophone positions in the water column due to tilt, an acoustic array positioning system was deployed with the vertical array. The array positioning hardware consisted of four acoustic transponders and a shipboard interrogation unit. Three transponders were deployed around the vertical array at a range of approximately 250 m in an approximate equilateral triangle configuration. Each transponder was bottom moored with ballast and sub-surface floats to keep the transponders a few meters (5.5 m) from the bottom.
fourth transponder was attached to the bottom of the vertical array. The time of arrival information obtained by analyzing the vertical array data (subset of eight hydrophones) from the four transponders was sufficient to localize the transponders with respect to each other and the array hydrophone positions in a local coordinate system. A detailed description of the array positioning system and methods is available in Ref. [17].

Estimates of array shape for the 26th at four time samples were calculated by the array positioning system. For the first three time samples the maximum deflection from vertical was on the order of 0.75 m and it occurred at the top of the array. For the fourth time sample the maximum was somewhat greater, i.e., 0.98 m, again at the top of the array. Estimates for the 27th at four time samples were also computed. On the 27th the average maximum deflection from vertical was on the order of 0.4 m, the location of the maximum deflection was in the mid portion of the array. This degree of deflection from vertical was sufficiently small with respect to a wavelength at the frequencies of interest that array shape correction was not required.

2.2. SOURCE AND SIGNAL CHARACTERISTICS
The stationary source was deployed approximately 5.6 km due north of the vertical array. The source was suspended from a buoy which was tethered to a ballast on the bottom. At the source location the bathymetry was measured to be 130 m.

One of the signals transmitted by the stationary source was a continuous transmission of pseudorandom noise (PRN) produced using a maximal length sequence (MLS) based on a six-bit shift register and bit length of 52.9 ms modulated onto a carrier with center frequency of 170 Hz. The repetition length for this sequence was 3.15 s, the –3 dB bandwidth was approximately 12 Hz, and the source level was approximately 163 dB re 1 μPa/√Hz. For further information on MLS see, for example, Ref. [18].

On the afternoon of the 27th a source ship towed a source from point A to point B, Fig. 1, at a speed of approximately 3.5 kn. One of the signals transmitted by the source was a PRN sequence similar to that discussed above. The source level was approximately 176 dB re 1 μPa/√Hz. This signal was transmitted for 30 s out of every minute.

Over the course of the two days the sources transmitted a variety of signal types in two frequency bands, a band from 160 to 180 Hz and from 320 to 350 Hz. For the analysis reported herein a signal in the 160 to 180 Hz band was selected. For the stationary source a 39 min sequence of the PRN signal was processed (15:44 to 16:23 on 26 October). For the moving source a 17 min sequence of the PRN signal was processed (14:41 to 14:58 on 27 October).
Figure 3 illustrates an example of the PRN signal in the frequency domain as a function of hydrophone number (odd numbered hydrophones only) for a 16 s sample. Note the discrete 'pickets' in frequency which are characteristic of the spectrum of PRN signals. Examining Fig. 3 it is seen that the signal-to-noise ratio is highly variable across the array and as a function of frequency. At the center of the band, slightly below 170 Hz, there is a 'picket' with energy across most of the array, this portion of the signal centered at 169.9 Hz was used throughout the analysis.

Figure 3  Spectrum for the stationary source PRN signal as received on the vertical array at $T = 0$ min, odd-numbered hydrophones only.
Genetic algorithms are based on an analogy with biological evolution. The basic principle of GA is simple: From all possible model vectors, an initial population of \( q \) members is selected. The fitness (one minus the object function) of each member is computed. Then through a set of evolutionary steps the initial population evolves in order to become more fit. An evolutionary step consists of selecting a parental distribution from the initial population based on the individual’s fitness. The parents are then combined in pairs, and operators are applied to them to form a set of children. The operators are the crossover and mutation operators. Finally the children replace part of the initial distribution to get a more fit population. For a detailed description of GA and their application to geoacoustic parameter estimation, see Ref. [13]

### 3.1. Baseline Environmental Model

The environmental model consisted of an ocean layer overlying a sediment layer and a bottom layer as shown in Fig. 4. All layers were assumed to be range-independent. For the purposes of the inversion the forward model parameters were subdivided into four parameter subsets: geometric, sediment, bottom and water sound-speed. The geometric parameters included source range, source depth, the depth of the receiver array and bathymetry. The baseline sediment and bottom properties used for the North Elba site were based on the work of Jensen [16], see Fig. 4. Note that the sediment and bottom parameters are average parameters determined by matching predicted transmission loss with measured transmission loss in the North Elba basin over a wide range of frequencies, see Ref. [16]. For this area Jensen [16] obtained good agreement between predicted and experimental propagation loss without including shear properties, thus shear properties were not included in the model. The water sound-speed profile was from a CTD taken near the vertical array on the morning of 26 October. As seen in Fig. 4 the water sound-speed profile was a summer profile, almost isovelocity down to 60 m and then a strong thermocline extending to about 80 m. Optimization was not carried out over the water sound-speed profile. The baseline value for receiver depth was based on the bathymetry measured at the array and the physical characteristics of the array and mooring, see Fig. 2.

The baseline forward model of Fig. 4 was used with the SAACLANTCEN normal mode propagation model, SNAP [19], to predict the normal mode structure for a source at 170 Hz at a depth of 80 m. The magnitude of the vector inner product of the depth sampled mode eigenfunctions and the SNAP-predicted pressure field at a
range of 5.6 km was evaluated. At this range, mode 2 was the dominant mode with modes 1 and 5 also contributing. Modes 6, 7 and 8 provided a contribution but at a much reduced level. Thus, the inversion was based primarily on the contribution of three modes.

3.2. OBJECT FUNCTION

The inverse problem was solved as an optimization problem; that is, find the model vector \( \mathbf{m} = \{m_i\} i = 1, 2, \ldots, p \) that minimized the object function. The object function was a function of the vector of observations \( \mathbf{q} \) and a vector of forward model predictions \( \mathbf{w}(\mathbf{m}) \), the following normalized Bartlett processor was used:

\[
P(\mathbf{m}; \omega_j) = \frac{1 - \mathbf{w}^*(\mathbf{m}) \hat{\mathbf{R}}(\omega_j) \mathbf{w}(\mathbf{m})}{\| \mathbf{w}(\mathbf{m}) \|^2},
\]

where \( \hat{\mathbf{R}}(\omega_j) \) is the data cross-spectral matrix formed from the observation vectors at a single frequency \( \omega_j \).

The time series data for the 48 hydrophones was used to estimate the cross-spectral matrices. The data for each hydrophone was transformed into the frequency domain using a Fourier transform. Since the data was acquired at a sample rate of 1 kHz and the transform length was 4096 samples the ‘bin’ width was 0.24 Hz. The cross-spectral matrix was formed near the center frequency of the signal band, 169.9 Hz. Each matrix was computed as an inner product of the observation vectors \( \langle \mathbf{q}^*, \mathbf{q} \rangle \) normalized by the norm of the observation vector squared. An average over two time epochs was computed, thus each matrix represented a total time sample of approximately 8 s. An estimate of the cross-spectral matrix was calculated at 1 min intervals over the stationary data time period yielding 40 cross-spectral matrix estimates.

3.3. MODEL PARAMETER ESTIMATION

There are a few GA parameters that must be defined for each GA application. Based on previous experience the following values were used in the analysis of the North Elba data, see [13]. The population size was set to 64, the reproduction size was 0.5, the crossover probability was 0.8, the mutation probability was 0.05, and the number of iterations (or forward model computations) was 2000. The forward model used was the range-independent SNAP model [19]. One ‘inversion’ consisted of 2000 iterations for each of ten independent parallel populations. Thus a total of 20,000 forward model computations were used for each inversion. At the completion of an inversion there were 320 model parameter vectors or population members resulting (population size times the number of parallel populations times the reproduction size).

The optimization was carried out using 12 parameters, see Table 1, the parameters are grouped into three subsets: geometric, sediment and bottom. Table 1 also provides the search bounds used for each parameter. For each parameter the search space was quantized into 128 increments. There was no optimization of the water sound-speed profile, a single sound-speed profile based on a CTD measurement at the array site was used. The interpretation of the parameters of Table 1 is quite straightforward except for ‘receiver depth’. The receiver depth is the depth of the deepest hydrophone, the GA used this parameter to optimize the vertical position of the entire vertical array in the water column.

Inversion for the 12 geometric and geoaoustic parameters was carried out for each of the 40 cross-spectral matrices. For each of the 40 samples the GA produced 320 model estimates for each parameter. Fig. 5 illustrates the mean of the GA estimates,
computed over the 320 most fit estimates, for each of the 12 parameters as a function of time. The range of values plotted is the same as the parameter search bounds. Since the source and receiver were both fixed the variability of the mean estimate as a function of time was used as a measure of consistency. It is seen that the geometric parameters, Fig. 5a, were fairly consistent over time, especially source depth. Examining Fig. 5b it is seen that the sediment parameter estimates were not consistent, even the upper and lower compressional speeds were highly variable. From Fig. 5c it is seen that the compressional speed for the bottom was consistent but the bottom density and attenuation estimates were not.

In order to obtain a single estimate for each of the 12 parameters the 320 parameter estimates for each of the 40 time samples were concatenated into one collection of samples. *A posteriori* probability distributions for each of the 12 parameters were estimated using the $320 \times 40$ samples, see Fig. 6. These distributions provide additional insight into the performance of the parameter inversion process. Clearly, the results provided by Figures 5 and 6 are closely related. They use the same data, but Fig. 5 emphasizes the variability of the estimates as a function of time whereas Fig. 6 emphasizes the variability over the search interval. It is seen that the source range and depth, bathymetry, receiver depth and compressional speed in the bottom are quite well determined. That is, the distributions are compact over the search interval and there is an unambiguous peak indicating that the inversion was fairly successful at finding a good fit for these parameters. The sediment layer was not very deep, less than one-third of a wavelength, thus the propagation was not sensitive to this layer and the sediment parameters were not well determined. As shown in Ref. [20] those parameters which were not well determined are also those parameters for which accurate knowledge is not required for source localization.

Based on the *a posteriori* probability distributions, three estimates for the model parameters are available: those associated with the largest fitness, those based on the peak of the distribution and those based on the mean of the distribution. Analysis of the estimated parameters has shown that the mean is the most robust thus it was used as the parameter estimate, see Table 2. Table 2 also contains the baseline parameters and a reliability measure which indicates how well each parameter has been determined. The reliability measure is the standard deviation of the distribution expressed as a fraction of the search interval for each parameter. This measure describes how well the estimates are clustered within the search interval. The reliability measure supports the conclusions discussed above that the geometric parameter estimates are consistent, that the sediment estimates are not consistent, and that the bottom compressional speed estimate is very consistent.

Comparing the baseline model parameters with the GA estimated parameters it is apparent that there are some differences between the baseline and estimated values. For the geometric parameters the estimated location of the deepest hydrophone differs by one meter from the measured value. The estimated bathymetry is an 'average' bathymetry as seen by the acoustic field. The estimated value falls between the measured values at the source and receiver. The geoacoustic values are also
Figure 5  Mean of the GA parameter estimates as a function of time: (a) geometric, (b) sediment, and (c) bottom parameters.

somewhat different. This is not surprising since the baseline geoacoustic values are average values obtained by averaging over a wide range of frequencies and ranges, whereas the estimated values were obtained at a single frequency and range.

Stationary source localization

In this section we examine the performance of matched-field processing for estimation of source location parameters using the vertical array data obtained during the October 1993 sea trial. The standard Bartlett processor was used to generate estimates of source range and depth. The Bartlett processor was computed using both the baseline and GA estimated values for the forward model parameters. A search over source range and depth was performed to generate ambiguity surfaces. The location of the maximum of the ambiguity surface was used as the source location parameter estimate. The Bartlett processor was normalized such that a perfect match between the predicted field and the observed field yielded a maximum value of 0 dB, see Eq. (1). The analysis was carried out for a single frequency centered at 169.9 Hz. The water sound-speed profile was that shown in Fig. 4 measured at the vertical array site on the morning of the 26th.

The data was the 39 min sample (48 hydrophones) of the PRN signal collected using the stationary source on 26 October (same data as used by the CA to estimate model parameters). The hydrophone positions were not corrected for tilt, the acoustic positioning estimates of array shape indicated that the tilt was always less than one degree. Based on the known uncertainties about the GPS position for the vertical array and the source buoy the source range with respect to the vertical array was predicted to be 5600 ± 200 m. The accuracy of the knowledge about the source depth would lead to a prediction of 80 ± 2 m.

4.1. PERFORMANCE VS MODEL

Comparing the model parameters of Table 2, i.e., the baseline and the GA estimated parameters, it was of interest to understand which model parameters were important with respect to obtaining a good field match between the predictions and the field observations. As a starting point the 40 samples of the PRN signal were processed using a number of model vectors. The search space was limited to a small region containing the source, 5–6 km in range and 10–100 m in depth. Figure 7 is the power of the Bartlett processor at the maximum of the ambiguity surface as a function of time. Line (1) is the result obtained evaluating the Bartlett power vs time using the baseline model. Line (2) illustrates the power when the GA estimated bathymetry and receiver depth are used in place of the baseline values. Comparing line (1) with line (2) it is seen that using the GA estimated values produced a better match. By changing the bathymetry from 127 m to the estimated value of 128.9 m and the receiver depth from 112.7 m to 111.7 m the mean Bartlett power increased from
Figure 7  Bartlett power at the surface maximum as a function of time for the stationary source using (1) baseline model, (2) baseline with GA estimated bathymetry 128.9 m and receiver depth 111.7 m, (3) baseline with GA estimated bathymetry 128.9 m, receiver depth 111.7 m and sediment parameters, (4) all GA estimated parameters (search region 5–6 km, 10–100 m).

-2.7 to -0.9 dB. Most of the improvement was due to the estimate of bathymetry. Using only the bathymetry estimate the mean Bartlett power was -1.2 dB. Line (3), mean power of -0.6 dB, is the result obtained using the baseline model augmented with the GA estimated values for bathymetry, receiver depth and the sediment parameters. Finally, line (4) provides the Bartlett power when all of the GA model parameters were used. For this case the mean Bartlett power was -0.3 dB, since 0 dB represents a perfect match, this implies that the GA estimated parameters provided a good fit to the actual environmental parameters at the trial site at this frequency.
4.2. SOURCE LOCALIZATION

Ambiguity surfaces were computed over a search region of 1–10 km in range ($\Delta r = 62.4$ m) and 10–100 m in depth ($\Delta d = 0.625$ m) using the baseline model and the GA estimated model for all 40 time samples. Figure 8 illustrates an ambiguity surface calculated using an 8 s data sample for both the baseline model and the GA estimated model. All ambiguity surfaces looked essentially identical to these two surfaces. The maximum of the ambiguity surfaces, using the GA estimated model, was constant at 5430 m in range and 75.6 m in depth for all 40 time samples. This source location estimate was quite close to the actual. As previously discussed the actual source location was predicted to be $5600 \pm 200$ m in range and $80 \pm 2$ m in depth. The maximum-to-largest sidelobe ratio was about 1 dB for all 40 time samples. For the surfaces based on the baseline model the maximum was at 1748 m in range and 90.6 m in depth for almost all of the surfaces. The second largest maximum was located at 6803 m and 86 m, there was not a local maximum near the source location. Comparing the two ambiguity surfaces it is apparent that the sidelobe structure was reduced substantially when the GA estimated parameters were used.

The use of the estimated forward model parameters improved the localization for the stationary source. Even in a region such as the North Elba site where a good average geoacoustic model had previously been estimated, the source localization was improved considerably through the use of inversion of the acoustic data for forward model parameters. Fig. 7 clearly illustrated that accurate estimates of the receiver depth and bathymetry were very important.

(a) baseline model and (b) GA estimated model, at $T = 0$ min.
Moving source localization

On the afternoon of 27 October 1993 a source was towed from point A to point B, Fig. 1, at a speed of approximately 3.5 kn. The depth of the source was monitored on board the source ship using a pressure sensor mounted on the source. The range of the source ship from the vertical array was estimated using GPS positions recorded on board. A PRN signal with a center frequency of 170 Hz was transmitted for about 20 min. Every minute a transmission lasting 30 s was sent out. Eighteen samples of this signal have been analyzed in the same manner as the stationary source data. Cross-spectral matrices based on an 8 s observation were computed at 1 min intervals.

Ambiguity surfaces were computed for the 18 time samples using the baseline and GA estimated model parameters. The surfaces were computed over a search region of 5–10 km in range ($\Delta r = 62.4$ m) and 10–100 m in depth ($\Delta d = 0.625$ m). For each time sample the range and depth positions for the surface maximum were used as the source location estimates. Figure 9 illustrates these estimates as a function of time along with the actual positions for the source ship. Only those estimates that were within the expected source range interval (5–8 km) and depth interval (60–80 m) are plotted. The Bartlett power corresponding to those estimates within that range/depth region are also provided.

It is seen from Fig. 9a that the range estimates based on the baseline model were fairly sparse. Only 8 of the 18 estimates were within the range/depth region, and for those there was a bias of 500 to 800 m. The range estimates based on the GA estimated model were consistent, only one estimate fell outside of the range/depth region. The bias in the range estimates was reduced to about 300 to 400 m. Figure 9b illustrates the depth estimates. Again the depth estimates based on the baseline model are sparse and do not track the actual source depth. The estimates based on the GA estimated model are quite good. In particular note the estimates within the first four minutes where the source is coming up, the matched-field estimates track the actual positions well.

Figure 10 illustrates examples of ambiguity surfaces computed using the moving source data for two time samples, one at the beginning of the data set and one near the end. The one at $T = 0$ min corresponds to a case where the maximum of the surface for the baseline model is not at or near to the source location. For the one at $T = 15$ min the maximum for the baseline model is near to the source location. In both cases the sidelobe level was reduced when the GA estimated model parameters were used.
Figure 9  Source locations and Bartlett power as a function of time. Actual source locations (squares), estimated source locations based on GA estimated model (triangles) and estimated source locations based on baseline model (circles) for the moving source: (a) range (b) depth and (c) Bartlett power.

Conclusions

Acoustic field data and environmental data were collected in shallow water in October 1993. A vertical receive array with acoustic array positioning was used along with a stationary and moving source. These data were used to evaluate the performance of field inversion methods for the estimation of environmental and source location parameters.

Genetic algorithms were first applied for the estimation of the geometric and geoacoustic parameters. Highly consistent estimates for bathymetry, receiver depths, and compressional speed in the bottom were obtained. Reasonable estimates were obtained for the other environmental parameters. These estimates were used for the forward model parameters required for performing matched-field source localization. Specifically, field observations for a stationary source were used to invert for the forward model parameters that are required to support matched-field source localization. The estimated forward model parameters were then used in a standard Bartlett processor to accurately localize a moving source in range and depth over a range interval of 5.8–7.7 km. The use of the GA estimated geometric and geoacoustic parameters improved the source localization performance considerably.

The application of global methods for estimation of the forward model parameters to support source localization has been shown to be necessary and effective in shallow water.

Inversion for geometric and geoacoustic parameters in shallow water: Experimental results

Abstract

Experimental results on the estimation of both geometric and geoacoustic parameters in shallow water are presented. Genetic algorithms are used for estimation of the forward model parameters, the estimated parameters are then used by a standard Bartlett processor for source localization. A stationary source at a range of 5.6 km and a moving source at ranges from 5.8 to 7.7 km were successfully localized in range and depth using a single frequency Bartlett processor. It is demonstrated that global estimation of the forward model parameters significantly improved source localization performance.
